#### 39 Abstract

40

41 Combining U–Pb and Lu-Hf isotopic data of detrital zircon grains has proven a powerful 42 tool to unravel the provenance of sediments and address continental crust evolution. In 43 this study, we explore the origin of thick siliciclastic metasedimentary units from the 44 high-grade internal domains of the Variscan belt of Europe and examine their 45 significance for Neoproterozoic crust formation and evolution along the North 46 Gondwana margin. We present data and U-Pb/Lu-Hf systematics of detrital zircons 47 from five amphibolite-facies metasediments sampled in the eastern French Massif 48 Central, measured in situ by LA-(MC)-ICP-MS. The sedimentary protoliths were 49 deposited in the Ediacaran as evidenced by field relationships and maximum 50 depositional ages ranging between 592.4 ± 5.5 and 556.8 ± 5.1 Ma. All samples 51 contain three main zircon populations in terms of age distribution and Hf isotopes: (i) abundant 0.55–0.65 Ga zircons with considerably scattered  $\epsilon Hf_{(t)}$  from -19 to +14; (ii) 52 varied amounts of 0.65–1.0 Ga zircons showing dominantly positive  $\epsilon Hf_{(t)}$  with the 53 54 exception of the c. 1.0 Ga zircons; and (iii) ≥ 1.8 Ga zircons (mostly between 1.9–2.1 and 2.5-2.8, up to 3.2 Ga) with EHf(t) ranging between +5 and -7. Multidimensional 55 56 scaling of our U-Pb dataset and a data compilation of Ediacaran to Lower Cambrian

(meta)sediments from the North Gondwana margin reveals that the relative proportions 57 58 of the three age components carry discriminant provenance information. Geological 59 data indicate that the Ediacaran basins of the eastern French Massif Central collected 60 the erosion products of two main source regions: (i) the Neoproterozoic Cadomian 61 magmatic arc; and (ii) the cratonic hinterland, mostly from the Saharan Metacraton and 62 the Arabian-Nubian Shield. Our dataset attests to the reworking of: (i) juvenile 63 Neoproterozoic crust and, (ii) old Paleoproterozoic to Neoarchean crustal components, 64 either as part of the detritus or incorporated in Neoproterozoic arc magmas. First-order 65 estimates derived from the isotopic signature of S-type granitic magmas sourced in the 66 Ediacaran metasediments suggest that 60–75% of the detritus would correspond to 67 young Neoproterozoic crust and thus represent net additions to the continental crust 68 volume.

72

#### 73 **1. Introduction**

74

75 Multi-methods studies based on surface heat flow measurements, seismic profiles and 76 large-scale geochemical surveys concluded that the continental crust has a bulk 77 andesite/diorite composition (e.g. Rudnick and Fountain (1995); Rudnick and Gao 78 (2003); Wedepohl (1995)). Importantly, such composition is not in equilibrium with a 79 mantle peridotite, meaning that new crust generation necessitates the addition of 80 mantle-derived magmas to a pre-existing crustal volume followed by differentiation of 81 the basaltic precursor and foundering of mafic residual materials into the mantle. This 82 hints that the hallmark of crust production is the intrusion of magmas extracted from

ultrabasic and young basic igneous sources (Condie and Aster, 2010). However, 83 84 addressing the rate of crust production based solely on the igneous record has proven 85 ambiguous because magmatic rocks are not always preserved and can experience 86 sedimentary reworking (lizuka et al., 2005). Consequently, continental sediments and 87 sedimentary rocks have been increasingly used to address the timing, rate and mode 88 of continental crust formation (see review in Dhuime et al. (2017)). In particular, many 89 studies focus on zircon, an accessory mineral of intermediate to felsic igneous rocks 90 characterized by its extreme resilience to mechanical abrasion and low to high-T 91 alteration such that it is very commonly retrieved as detrital grains in sedimentary 92 lithologies. Chronological constraints derived from detrital zircon U–Pb systematics 93 paired with the determination of Lu-Hf isotope compositions of individual grains offer 94 the possibility to gain insights on the age and origin of rocks that have been eroded and 95 thus to genuinely track periods of crust production (Gerdes and Zeh, 2006; lizuka et al., 96 2005; Kemp et al., 2006).

97

98 The basement of Western and Central Europe corresponds to a set of crustal blocks 99 amalgamated during the late Paleozoic Variscan s.l. collisional orogeny (Franke, 1989; 100 Kroner and Romer, 2013; Matte, 1986). Such blocks are often referred to as 101 'Cadomian-type peri-Gondwana terranes' since they were formerly located at the 102 northern margin of the Gondwana continent by the late Neoproterozoic and were 103 strongly shaped by the Cadomian accretionary orogen featuring a c. 2500 km-long 104 magmatic arc and associated back-arc basin (Garfunkel, 2015; Murphy and Nance, 105 1989; Murphy et al., 2004). Importantly, accretionary orogenic settings are generally 106 retained as the main sites of continental crust production as they encompass 107 voluminous mantle-derived magmatism (Cawood et al., 2009; Reymer and Schubert, 1984; Taylor and McLennan, 1985). Yet, within the Cadomian realm, today-exposed 108 109 mantle-derived volcanic-plutonic associations are scarce, in marked contrast with the

well-preserved coeval siliciclastic sedimentary successions deposited at the rear of the 110 arc (Dabard et al., 1996; Denis and Dabard, 1988; Drost et al., 2011; Garfunkel, 2015; 111 112 Linnemann et al., 2014; Linnemann et al., 2008; Orejana et al., 2015; Pereira et al., 2006; Pereira, 2014; Pereira et al., 2012a; Pereira et al., 2012b; Rabu et al., 1990; 113 Talavera et al., 2015; Talavera et al., 2012). Therefore, such sedimentary rocks would 114 have preserved the best record of the Cadomian orogenic evolution and constitute an 115 116 ideal target to clarify the extent of Neoproterozoic crust production along the North 117 Gondwana margin.

118

119 Several provenance studies based on heavy minerals or detrital zircon typology and U-120 Pb(-Hf) signatures have been carried out with the main aim to address the 121 Neoproterozoic paleogeography of the peri-Gondwana terranes, notably their paleo-122 location along the main Gondwana continent (e.g., (Chelle-Michou et al., 2017; Dabard 123 et al., 1996; Drost et al., 2011; Henderson et al., 2016; Pereira et al., 2012a; Pereira et 124 al., 2012b; Stephan et al., 2018). Investigations so far focused on areas having 125 experienced limited Variscan metamorphic overprint such as the Teplá-Barrandian and 126 Saxo-Thuringian zones of the Bohemian Massif (Drost et al., 2011; Hajná et al., 2017; Linnemann et al., 2007; Linnemann et al., 2014; Linnemann et al., 2017; Žák and 127 128 Sláma, 2017), the Central Iberian, Ossa-Morena and Cantabrian zones of the Iberian 129 Massif (Díez Fernández et al., 2010; Fernández-Suárez et al., 2014; Naidoo et al., 130 2017; Orejana et al., 2015; Pereira et al., 2012a; Pereira et al., 2012b; Talavera et al., 2015; Talavera et al., 2012; Teixeira et al., 2011; Zimmermann et al., 2015) and the 131 northern to central Armorican Massif (Ballouard, 2016; Dabard et al., 1996; Denis and 132 133 Dabard, 1988; Gougeon et al., 2017; Nagy et al., 2002; Rabu et al., 1990), all exposing (very) low to medium-grade Variscan metamorphic units (Fig. 1). In contrast, little is 134 135 known about the pre-orogenic evolution of the high-grade metamorphic belts building 136 up the Moldanubian zone, regarded as the most internal domain of the Variscan belt (Lardeaux et al., 2014). In this contribution, we report the U–Pb–Hf isotopic compositions of detrital zircon grains from amphibolite-facies metasediments from the eastern French Massif Central measured in situ by LA–(MC)–ICP–MS with the aim to address: (i) the Neoproterozoic paleogeography of this crust segment with respect to adjacent (para)autochtonous Variscan blocks; (ii) the source of the sedimentary supplies; (iii) the relative extent of crust production/reworking during the Cadomian orogeny.

144

#### 145 **2. Geological setting**

146

147 The eastern French Massif Central (EFMC, Fig. 2) exposes two main allochtonous tectonic-metamorphic units (nappes), juxtaposed as a result of collision between 148 Laurussia and Gondwana (Faure et al., 2009b; Ledru et al., 1989). The overlying Upper 149 150 Gneiss Unit comprises ortho- and paragneisses having experienced MP-M(H)T amphibolite- to granulite-facies collisional metamorphism at 360-340 Ma (Chelle-151 152 Michou et al., 2017). The base of this unit features a bimodal meta-igneous association 153 referred to as the Leptynite-Amphibolite Complex, which hosts petrological relicts of eclogite-facies metamorphism dated at c. 380 Ma in the SW part of the French Massif 154 155 Central (Lotout et al., 2018), presumably attesting to the closure by subduction of the Galicia-Massif Central oceanic domain. The underlying Lower Gneiss Unit consists of 156 an association of amphibolite-facies micaschists, ortho- and paragneisses with very 157 scarce amphibolites (Ledru et al., 2001). The Lower Gneiss Unit experienced 158 significant anatexis at the post-collisional stage (315-300 Ma, e.g. Mougeot et al. 159 (1997)), culminating in the formation of the 120 x 80 km large Velay granite-migmatite 160 161 dome during orogenic collapse (Ledru et al., 2001; Montel et al., 1992). The Velay 162 dome is overturned to the south onto the low-grade Parautochtonous Unit, largely

composed of greenschist- to lower amphibolite-facies metasediments. All metamorphic
units were intruded by a set of peraluminous to metaluminous granitoids, testifying for
protracted magmatic activity between 335 and 300 Ma (Couzinié et al., 2014; Laurent
et al., 2017; Villaros et al., 2018).

167

Available geochronological data on the protoliths of the metamorphic rocks from the 168 EFMC suggest contrasted pre-Variscan evolutions for each nappe. In the Upper 169 Gneiss Unit, both felsic and mafic meta-igneous lithologies are of Ordovician age (LA-170 ICP-MS U-Pb and Pb evaporation zircon ages; Chelle-Michou et al. (2017); Feybesse 171 172 et al. (1995)). Metasediments have not been investigated in the EFMC area but yielded 173 Cambrian maximum depositional ages in the western part of the French Massif Central (LA-ICP-MS U-Pb zircon; Melleton et al. (2010)). In the Lower Gneiss Unit, the 174 175 protoliths of the Velay Orthogneiss Formation (Fig. 2), an association of augen gneisses and leucogneisses regarded as former S-type granites, were emplaced at c. 176 541 Ma (LA-ICP-MS U-Pb zircon; Couzinié et al. (2017)), i.e. at the Ediacaran-177 178 Cambrian transition. Field relationships indicate that these (meta)granites are intrusive 179 within the (meta)sediments of the Lower Gneiss Unit (Ledru et al., 1994) entailing that the latter were deposited in the Precambrian. The abundance of Neoproterozoic 180 181 inherited zircon cores in the Velay Orthogneiss Formation and other crust-derived 182 Variscan granitoids point to a Neoproterozoic crustal source which likely corresponds 183 to the metasediments (Couzinié et al., 2017; Laurent et al., 2017). This view is consistent with the preliminary results of Chelle-Michou et al. (2017) who obtained 25 184 concordant Neoproterozoic U-Pb zircon dates from a Lower Gneiss Unit paragneiss. 185 186 Finally, deposition of the thick siliciclastic successions of the Parautochtonous Unit was bracketed by LA-ICP-MS U-Pb zircon dating of interlayered felsic volcanics, all 187 188 yielding Ordovician ages (Faure et al., 2009a).

189

# 190

#### 3. Samples and analytical techniques

191

The sampling strategy was to cover all the metasedimentary units wrapping the Velay migmatite-granite dome, which cores the Lower Gneiss Unit in the EFMC. Five amphibolite-facies metasediments were collected. GPS coordinates and whole-rock major and trace element compositions of the investigated samples are available in Supplementary Table S1. The latter were obtained from the ALS Global firm (details on the procedure and accuracy/reproducibility in Supplementary Material).

198 PIL-16-01 belongs to a 40 cm-thick metasandstone body interbedded within the aluminous Pilat micaschists (Malavielle et al., 1990), which form a constituent lithology 199 200 of the Lower Gneiss Unit in the northern part of the Velay Complex (Fig. 2). This very 201 silicic rock (SiO<sub>2</sub> > 87%) is dominantly composed of quartz and muscovite with 202 subordinate amounts of feldspar, Fe-Ti oxides and zircon (Fig. S1a). The metamorphic 203 evolution has been constrained on surrounding metapelites and features an early stage 204 at 8–10 kbar and  $600 \pm 50^{\circ}$ C followed by equilibration at 3–5 kbar and  $690 \pm 20^{\circ}$ C 205 (Gardien, 1990).

206 *SEN-16-01* corresponds to a meter-thick quartz-rich layer within the Senouire 207 micaschists, a typical metasedimentary unit of the western flank of the Velay Complex 208 (Ledru et al., 1994). The specimen is mostly composed of quartz and biotite with minor 209 amounts of muscovite, garnet, plagioclase, Fe–Ti oxides and zircon (Fig. **S1b**). Peak 210 metamorphic conditions for this unit have been estimated at 630  $\pm$  20°C and 5–6 kbar 211 (Mintrone, 2016).

212 *CHA-16-02* was sampled from a 20 cm-thick meta-arkose layer closely associated with 213 amphibolite-facies micaschists from the southwestern part of the Velay Complex 214 (Briand et al., 1993). The rock is clearly a meta-arkose because of its moderate 215  $SiO_2/Al_2O_3$  and  $Fe_2O_3/K_2O$  ratios (lower than 6 and 0.7 respectively; Herron (1988)) and

the high modal proportion of feldspar which, together with quartz, constitutes most of
the rock. Other minerals include garnet, muscovite, Fe–Ti oxides and zircon (Fig. S1c). *TN46* is a coarse-grained, anatectic paragneiss collected in the eastern part of the
dome in the Tournon area (Fig. 2) and already described in Chelle-Michou et al.
(2017). The sample is dominantly composed of quartz, plagioclase, alkali-feldspar and
biotite together with scarce sillimanite.

*PdB-16-01* is an anatectic paragneiss taken from the migmatite exposure of Pont de-Bayzan in the southern part of the dome (described in Montel et al. (1992)). Only the melanocratic part of the sample, presumably corresponding to residuum in the sense of Sawyer (2008), was selected for zircon analysis. The mineral assemblage consists of quartz, plagioclase, alkali-feldspar and biotite with accessory zircon, monazite and apatite (Fig. **S1d**). According to Montel et al. (1992), partial melting took place at 650– 720°C and 3–4.5 kbar.

229

230 Zircon grains were separated from crushed rock samples using standard techniques at 231 Saint-Etienne University, described in Couzinié et al. (2016). More than 100 and up to 232 300 randomly selected grains were cast in epoxy resin and polished down to an 233 equatorial grain section. Cathodoluminescence imaging was performed at (i) the 234 Laboratoire Magmas et Volcans in Clermont-Ferrand, France using a Jeol JSM-5910 235 and (ii) the University of Bristol, UK using a Hitachi S-3500N SEM. Zircon U-Pb 236 isotopic analyses were carried out at ETH Zürich, Switzerland by laser ablation-237 inductively coupled plasma-sector field-mass spectrometry (LA-ICP-SF-MS) using a 238 RESOlution (ASI, Australia) 193 nm ArF excimer laser system coupled to an Element 239 XR (Thermo Scientific, Germany) sector-field mass spectrometer. Lu-Hf isotope measurements were performed at the Laboratoire Magmas et Volcans using a Thermo 240 241 Scientific Neptune Plus multi-collector ICP-MS coupled to the same RESOlution 193 242 nm laser excimer system as described above. Comprehensive descriptions of the

243 methodologies, results of secondary standard and sample measurements for both U244 Pb and Lu-Hf isotopes are available as Supplementary Material and Supplementary
245 Table S2 to S5.

246

247 **4. Results** 

248

- 249 4.1 Zircon description
- 250

251 Zircon grains in the investigated samples are mostly colorless, a few of them being 252 pinkish or yellowish. Their shapes vary from rounded (notably in sample PIL-16-01) to 253 sub-idiomorphic (sample PdB-16-01) with aspect ratios up to 1:3. They range in length 254 from 50 to 160 µm except in sample TN46 from which markedly larger grains were 255 extracted (100 to 300 µm long). The zircon grains are often broken (particularly in samples PIL-16-01 and SEN-16-01). Cathodoluminescence images reveal very diverse 256 257 internal structures (Fig. 3). Oscillatory or patchy, broad zoning is common in many 258 grains (see for instance in PdB-16-01, Fig. 3e). Core-rim relationships are frequent in sample TN46 (e.g. z19, z54 and z84 in Fig. 3d) but generally lacking in other samples 259 260 in which only very few crystals show narrow CL-bright or dark rims (< 10 µm-wide, see 261 zircon z83 and z35, Fig. 3a, or z11, Fig. 3b). Secondary textures include healed cracks and fractures (e.g. z35, Fig. 3a) and zones of blurred oscillatory zoning (e.g. z146, Fig. 262 263 3c), which were avoided for U-Pb dating. Otherwise, we did not target any specific 264 population in an attempt to be representative of the overall zircon diversity.

265

266 4.2 U–Pb geochronology

267

A total of 745 U–Pb measurements were performed on zircon grains from the five metasediments. Only dates concordant at 95–105% (with concordance defined as  $^{206}Pb/^{238}U$  date /  $^{207}Pb/^{206}Pb$  date x 100) will be further considered for interpretation (representing 492 individual analyses). The  $^{206}Pb/^{238}U$  dates are reported when younger than 1.2 Ga; the  $^{207}Pb/^{206}Pb$  dates are preferred when older. The preliminary zircon U–Pb–Hf data obtained by Chelle-Michou et al. (2017) on sample TN46 were appended to our new dataset of 67 U–Pb analyses on this sample.

275

276 The detrital zircon date distributions of all samples feature a dominant Ediacaran to late 277 Cryogenian population in the range 550–720 Ma representing between 50 and 75% of the dates and defining a prominent peak at c. 635 Ma (Fig. 4, 5). The remaining 278 279 analyses are mostly distributed over three main periods: 760-1050 Ma (Tonian to late 280 Stenian), 1.7–2.1 Ga (Paleoproterozoic) and 2.6–3.2 Ga (Neo- to Paleoarchean). PIL-16-01 and CHA-16-02 show similar detrital zircon date distributions, with the 281 282 Ediacaran-Cryogenian and Tonian-Stenian populations representing c. 70% and 14% of the dataset, respectively (Fig. 4a,c and 5a,c). Paleoproterozoic and Archean dates 283 284 are relatively scarce (< 12% and 6%, respectively). Sample SEN-16-01 differs by a larger proportion of 760-1050 Ma and older-than-1.8 Ga grains (18 and 23%, 285 286 respectively, Fig. 5b). TN46 paragneiss contains very few Tonian-Stenian grains but 287 an abundant Paleoproterozoic-Neoarchean population (36%, Fig. 5d), with dates up to 288 3.27 Ga (spot z7). The zircon U–Pb date spectrum of PdB-16-01 contrasts with that of 289 the other samples because: (i) Tonian-Stenian grains are more abundant than in any 290 other sample, representing 38% of the dataset; and (ii) Paleoproterozoic and Neoarchean dates are very scarce (only 4% of the data) (Fig. 5e). CL-dark zircon 291 292 grains yielding Variscan dates in the range 320-305 Ma were retrieved in sample 293 TN46, as already described and discussed by Chelle-Michou et al. (2017).

295

4.3 Zircon Hf isotope compositions

296

297 The zircon grains analyzed for Lu-Hf isotopes were selected as to representatively

capture the zircon date distribution for each sample. The results are depicted Fig. 6.

299

300 *PIL-16-01.* Twenty-two 550–665 Ma zircon grains show very diverse  $\epsilon$ Hf(t), from +8.7 301 down to -10.5. One late Tonian grain has a radiogenic  $\epsilon$ Hf(t) of +4.6. Early Tonian to 302 late Stenian zircons also have variable Hf isotope signatures with 3 grains displaying 303  $\epsilon$ Hf(t) of -11.9, +1.6 and +10.8  $\epsilon$ -units. Five Paleoproterozoic zircons range between -304 7.4 and +4.0  $\epsilon$ -units. Three Neoarchean grains are chondritic to suprachondritic, with 305  $\epsilon$ Hf(t) ranging from -0.4 up to +4.1.

306

307 *CHA-16-02.* The Hf isotope signature of 32 Ediacaran–Cryogenian zircons (565–720 308 Ma) is highly scattered with  $\epsilon$ Hf(t) ranging from -16.9 up to +12.7. Tonian–Stenian 309 (n=6) and Paleoproterozoic (n=1) grains display chondritic to supra-chondritic  $\epsilon$ Hf(t) 310 (between +0.5 and +12.3). Three Neoarchean zircons are nearly chondritic with  $\epsilon$ Hf(t) 311 ranging between -2.0 and +1.2.

312

313 *PdB-16-01.* Zircons with U–Pb dates in the range 590–980 Ma have dominantly very 314 radiogenic Hf isotope signatures: 84% of the data yield  $\epsilon$ Hf(t) higher than +4.4, and 315 47% show values overlapping with those for the Depleted Mantle (up to +13.7). Beside 316 this, 8% are nearly chondritic (between -1.8 and 1.2) and the remaining 8% 317 subchondritic (between -12.1 and -18.7). Paleoproterozoic zircon grains show slightly 318 non-radiogenic signatures ( $\epsilon$ Hf(t) of c. -2). Two Neoarchean grains yielded sub and 319 suprachondritic values of -5.6 and +2.6.

320

321 *TN46.* Results for this sample were obtained by Chelle-Michou et al. (2017) and are 322 briefly summarized hereafter. Zircon grains with U–Pb dates in the range 560–650 Ma 323 show very scattered  $\epsilon$ Hf(t) ranging from +5.6 down to -19.1. Two early Cryogenian– 324 Tonian grains have identical and very radiogenic Hf isotope signatures of +7.5. Four 325 Paleoproterozoic grains display unradiogenic signatures with  $\epsilon$ Hf(t) between -3.0 and -326 15.5. Archean zircons have chondritic to negative  $\epsilon$ Hf(t) between +0.2 and -4.2.

327

328 *General pattern.* The  $\varepsilon$ Hf(t) measured on Paleoproterozoic and Archean zircon are 329 highly scattered from sub to suprachondritic values. Detrital zircons crystallized at the 330 Tonian–Stenian boundary have even more diverse signatures with  $\varepsilon$ Hf(t) ranging from -331 19 up to +11 (in the field of composition expected for the Depleted Mantle reservoir). A 332 large majority of early Cryogenian–Tonian zircons (mostly represented by sample Pdb-333 16-01) have very radiogenic Hf isotope signatures. Ediacaran–late Cryogenian zircon 334 grains are typified by their highly variable  $\varepsilon$ Hf(t), from -19.1 up to +12.2.

335

#### 336 **5. Discussion**

337

5.1 Interpretation of U–Pb dates: depositional ages of the sedimentary
 protoliths and Variscan overprint

340

Field relationships indicate that (meta)granites from the Velay Orthogneiss Formation are intrusive within the (meta)sediments of the Lower Gneiss Unit (Ledru et al., 1994). The oldest emplacement age determined for the metagranite samples (545.9  $\pm$  4.3 Ma, leucogneiss MM09; Couzinié et al. (2017)) entails that the minimum depositional age of the sediments is Ediacaran. One single spot (#116) from a zircon grain in sample PIL-16-01 yielded a concordant date that is significantly younger than this inferred minimum

deposition age, i.e.  $526 \pm 5$  Ma (Fig. 5a). This zircon grain is therefore regarded as an 347 348 outlier, which possibly experienced Pb loss. Excluding this grain, all dates are older 349 than c. 545 Ma, so that the youngest zircon population in each sample can be 350 reasonably considered as representative of the maximum deposition age. The latter 351 has been estimated via the following procedure. First, the youngest (and older than c. 352 545 Ma) concordant analysis is identified. A Concordia date is then calculated out of it 353 and the closest older analysis. If the MSWD of concordance and equivalence lies in the 354 range of acceptable values (which depends on the number of analyses, see Spencer et 355 al. (2016)), the dates are statistically indistinguishable. The next older analysis is then 356 added to this pool and a new Concordia date calculated. This procedure is repeated until the MSWD falls out of the acceptable range. Maximum depositional ages range 357 358 from 592.4 ± 5.5 Ma for sample PdB-16-01 down to 556.8 ± 5.1 Ma for PIL-16-01 (Fig. 4). Samples SEN-16-01, CHA-16-02 and TN46 show intermediate (and identical) 359 maximum depositional ages of 567.7  $\pm$  6.0, 568.3  $\pm$  4.9 and 566.3  $\pm$  6.2 Ma, 360 361 respectively.

362

363 Among the five samples, zircon grains yielding Variscan dates were only retrieved from 364 the anatectic paragneiss TN46 for which a Concordia date of  $307.3 \pm 5.1$  Ma 365  $(MSWD_{C+E} = 1.3)$  can be calculated out of three equivalent analyses. Following Chelle-366 Michou et al. (2017), we interpret this date as reflecting the age of partial melting in this 367 part of the Lower Gneiss Unit. Apart from this sample, our dataset is indicative of scant 368 zircon neo- and/or re-crystallization during Variscan metamorphism as Variscan grains 369 are commonly lacking and overgrowth zones are scarce and narrow. Even though the 370 investigated samples equilibrated at amphibolite-facies conditions, reaching partial 371 melting for two of them, the Variscan imprint on the zircon budget remained very 372 limited, and the zircon age distribution clearly records the pre-Variscan evolution of the 373 protoliths.

5.2 The Ediacaran paleogeography of the EFMC with respect to other
Variscan zones

In this section, we aim to identify the provenance of the crustal segment that 377 constitutes the high-grade Lower Gneiss Unit of the EFMC by addressing its 378 paleographic relationships with adjacent, non-metamorphic to low-grade Variscan 379 zones. For this purpose, we compiled the results of 19 detrital zircon studies conducted 380 on Ediacaran to Lower Cambrian (meta)sediments from several Variscan zones (Fig. 381 382 1) and compared the detrital zircon date distributions to those observed in the EFMC. Comparison was quantified by non-metric multidimensional scaling (MDS) (Borg and 383 Groenen, 2005), a statistical technique recently expanded to the field of provenance 384 385 studies (Vermeesch, 2013). A total of 54 samples were retained based on the cut-off criterion "at least 51 zircon dates concordant at 95-105%" (with concordance defined 386 as <sup>206</sup>Pb/<sup>238</sup>U date / <sup>207</sup>Pb/<sup>206</sup>Pb date x 100), which corresponds to the number of grains 387 needed to be certain at 95% that no fraction representing more than 10% of the actual 388 population has been missed (Vermeesch, 2004). Calculations were computed using 389 the open-source R language (Ihaka and Gentleman, 1996) and the package 390 391 provenance (Vermeesch et al., 2016). As the U-Pb data were obtained from several 392 laboratories, with different analytical methods (LA-ICP-MS, SHRIMP) and associated 393 analytical uncertainties, we used the Sircombe-Hazelton L2-norm (Sircombe and 394 Hazelton, 2004) as dissimilarity measure, as recommended by Vermeesch (2018). The 395 resultant MDS "map" is displayed figure 7a.

396

Two major parameters control the variability of the U-Pb date distributions in Ediacaran–Lower Cambrian (meta)sediments from the North Gondwana margin:(i) the proportions of  $\geq$ 1.8 Ga zircons (captured by Dim<sub>1</sub>); and (ii) the relative importance of

15

the Ediacaran–late Cryogenian (<0.65 Ga) vs. early Cryogenian-Tonian (0.65-1.0 Ga)</li>
zircons in the Neoproterozoic population (Dim<sub>2</sub>) (Fig. **7b**). Specifically, the higher the
value of Dim<sub>1</sub>, the greater the proportions of zircons with Paleoproterozoic and older U–
Pb dates. Samples with elevated Dim<sub>2</sub> (such as NE13–1) feature a unimodal Ediacaran
date peak, whereas detrital zircon dates from low-Dim<sub>2</sub> samples (e.g. PNC1) are more
evenly distributed throughout the Ediacaran–Tonian time interval.

406

407 In the Dim1-Dim2 projection, Ediacaran-Lower Cambrian (meta)sediments from each 408 Variscan zone plot within restricted domains (Fig. 7a). Importantly, samples from the Lower Gneiss Unit of the EFMC display a large variety of detrital zircon date 409 410 distributions among this North Gondwana scheme. Paragneiss sample TN46 contains little 0.65-1.0 Ga zircon but a significant proportion of older-than-1.8 Ga grains, a 411 412 pattern similar to those observed in Ediacaran–Lower Cambrian (meta)sediments from the Bohemian Massif. In contrast, samples PdB16-01 and SEN16-01 are akin to 413 414 (meta)sediments of the Central Iberian Zone, being particularly characterized by the abundance of 0.65-1.0 Ga zircons. PIL16-01 and CHA16-01 plot in an intermediate 415 416 position with respect to these two endmembers. Altogether, the samples from the 417 EFMC Lower Gneiss Unit straddle the fields outlined by all the other Variscan zones 418 and no perfect match exists with any of them. Consequently, if the EFMC 419 metasediments were originally part of a single sedimentary basin (as suggested by 420 geological evidence), such basin can be regarded as a singular Ediacaran paleogeographic domain. The marked variations of the detrital zircon date distributions 421 422 between individual samples of the EFMC can be interpreted in two different ways. A 423 first possibility would be to consider that they reflect lateral and local variations of the sediment supply within the Ediacaran basin. Alternatively, they could indicate an 424 425 evolution of the sources of the detritus throughout the Ediacaran (of which timescales 426 cannot be captured within the precision of the LA-ICP-MS dating and the lack of

427 stratigraphic relationship between the samples), i.e. changes in paleo-streams and/or
428 tectonic setting delivering eroded materials from at least two different areas.

429

430 5.3 Zircon sources

431

Multi-methods studies (encompassing geochemistry, petrography, sedimentology, 432 433 geochronology) have demonstrated that Ediacaran sediments deposited along the northern margin of Gondwana were of mixed origin. A fraction of the detritus originated 434 435 from the erosion of the Cadomian magmatic arc and the rest was supplied by a 436 composite inland Gondwana-derived source (Abbo et al., 2015; Dabard et al., 1996; 437 Denis and Dabard, 1988; Drost et al., 2011; Linnemann et al., 2014; Linnemann et al., 438 2008; Orejana et al., 2015; Pereira et al., 2012a; Pereira et al., 2012b; Rabu et al., 439 1990). However, there is no consensus on the relative extent of proximal vs. distal 440 supplies and the actual nature of the hinterland source. Several authors propose that 441 each peri-Gondwana terrane received distal detritus from specific domains of Gondwana such as the Amazonian Craton, West African Craton, Saharan Metacraton 442 443 and Arabian Nubian Shield (Dörr et al., 2015; Henderson et al., 2016; Stephan et al., 2018). Yet, the case of the Lower Gneiss Unit of the EFMC is still disputed as 444 445 Henderson et al. (2016) and Stephan et al. (2018) argue for a West African Craton 446 supply while Chelle-Michou et al. (2017) retain a Saharan Metacraton provenance. In 447 addition, none of those authors discuss the extent to which the erosion of the Cadomian magmatic arc contributed to the observed detrital zircon age distributions in 448 the EFMC. In this section, we therefore (i) review the geological and isotopic 449 450 characteristics of the Cadomian arc and address its potential implication as a proximal 451 source for the Ediacaran EFMC sediments; and (ii) further discuss the nature of the distal source based on the newly obtained, extensive dataset. 452

454 The largest and best preserved exposures of the Cadomian magmatic arc crop out in 455 the northern Armorican Massif (France and British Channel Islands, see Ballèvre et al. (2001); Brown (1995); Chantraine et al. (2001); Strachan et al. (1996)). Even though 456 457 the exposed rocks may not correspond to those eroded at Ediacaran times, they can still provide constraints on the nature, age pattern and isotopic signature of the 458 proximal detritus. In this crust segment, igneous rocks include: (i) late Cryogenian to 459 460 early Ediacaran (660-560 Ma) calc-alkaline suites comprising basic, intermediate and acid components with radiogenic to unradiogenic Nd-Hf isotope signatures, taken as 461 462 evidence for arc-back-arc magmatism; (ii) late Ediacaran migmatites and peraluminous granitoids (the Mancellian batholith, 560-540 Ma), proposed to have been generated 463 during back-arc basin inversion and resulting arc-continent collision. Scarce 464 Paleoproterozoic and Tonian crustal rocks (Icartian and Pentevrian gneisses, 465 respectively) are also documented. Figure 8a,b presents a compilation of intrusion 466 ages available for igneous rocks from the northern Armorican Massif and obtained via 467 different geochronological methods (zircon and monazite U-Pb dating by LA-ICP-MS, 468 469 SIMS, EPMA and TIMS on single grains or multi-grain fractions for the latter technique, 470 whole-rock Rb-Sr). The observed age populations (540-750, c. 1800 and 2000-2200 471 Ma) are partly consistent with the spread of U–Pb dates in the detrital zircon record of 472 the EFMC. Importantly, the two subpeaks at 585 and 615 Ma observed in the latter 473 perfectly match the igneous dataset. Magmatic rocks emplaced in the time period 625-474 750 Ma are present, but scarce in the Armorican Massif. This may reflect either a 475 sampling bias or the fact that Cadomian subduction and related magmatism were not 476 yet active at that time (as suggested by the Cadomian geological record elsewhere in 477 Europe, e.g. Garfunkel (2015)). The  $\varepsilon$ Hf(t) of various Cadomian intrusions are depicted 478 in figure 8c (from Hf isotope studies or recalculated from Nd isotopes based on the 479 relation  $\epsilon$ Hf(t) = 1.36  $\epsilon$ Nd(t) + 3 determined by Vervoort et al. (1999)). Magmas

emplaced in the time period 750-620 Ma have supra-chondritic, DM-like Hf isotope 480 481 signatures. A clear shift towards less radiogenic source compositions occurred in the 482 Ediacaran, as magmas younger than 620 Ma show a broad range of inferred EHf(t) from +5 down to sub-chondritic values of -11. In general, a large spread of radiogenic 483 484 isotope signatures at a given time period is interpreted to reflect the contamination of 485 juvenile magmas by old crustal remnants via AFC-type processes and/or magma or source mixing as observed in many arcs built up on ancient continental crust (Bolhar et 486 al., 2008; Kelemen et al., 2003; Kemp et al., 2006). 487

Such a pattern is similar to that observed in the detrital zircon record of metasediments 488 489 from the Lower Gneiss Unit, yet slightly offset in time (to younger ages in the case of 490 Armorican rocks, Fig. 8c). The case of Tonian-Stenian, Paleoproterozoic and Archean 491 zircon grains is more problematic as there are no rocks of such ages or appropriate 492 isotopic signatures in the Armorican Massif. There, Paleoproterozoic granitoids have 493 suprachondritic, DM-like, EHf(t) which are more elevated than those observed in detrital 494 zircons from the EFMC Ediacaran (meta)sediments (Fig. 8c). Altogether, these 495 observations indicate that, our present state of knowledge, erosion of the Cadomian arc alone unsatisfactorily explains the U-Pb-Hf systematics of the EFMC detritus thus 496 497 calling for the existence of an additional zircon source i.e. the main Gondwana land 498 (Drost et al., 2011; Linnemann et al., 2014; Linnemann et al., 2008; Orejana et al., 499 2015; Pereira et al., 2012a; Pereira et al., 2012b).

500

501 By the mid-Ediacaran, the northern part of Gondwana had just been assembled and 502 stabilized following the late Cryogenian–Ediacaran Pan African orogenies (see 503 Garfunkel (2015)). The Gondwana crust (Fig. **9**) typically comprises cratonic domains 504 of Paleoproterozoic to Archean age (West African, Congo, Chad, Al Kufrah, Murzuq 505 cratons, see Liégeois et al. (2013)) and several Pan African mobile belts (Anti-Atlas, 506 Trans-Sahara and Oubanguides belts, East African orogen, Saharan Metacraton).

507 Most Pan African belts are composed of reworked cratonic crust ("metacraton") and 508 remnants of 850-620 Ma-old subduction zone-type magmatic activity (oceanic arc 509 accretion, continental arc systems) predating voluminous syn- to post-collisional magmatism at 620-570 Ma (Caby, 2003; Liégeois et al., 2003; Triantafyllou et al., 510 511 2016). Remobilization of ancient Paleoproterozoic to Archean crust is notably fingerprinted by the highly variable  $\varepsilon Nd(t)$  displayed by Ediacaran to late Cryogenian 512 igneous rocks from the Trans-Sahara (Liégeois et al., 1998; Liégeois et al., 2003), Anti-513 Atlas (Errami et al., 2009), and Oubanguides (Toteu et al., 2001) belts. Only the 514 Arabian-Nubian-Shield crust segment can be regarded as a juvenile Neoproterozoic 515 terrane (Stern, 2002). In the following, we attempt to identify the areas that would have 516 517 delivered distal detritus to the EFMC Ediacaran basins based on the igneous record of northern Gondwana. 518

519

520 Clearly, a supply from western African terranes must be disregarded because: (i) 521 Paleoproterozoic rocks from the West African Craton have suprachondritic Hf isotope 522 signatures whereas zircon grains of that age in the EFMC show a broad range of  $\varepsilon$ Hf(t) 523 (Fig. 6); (ii) Tonian rocks from the Trans-Sahara belt show subchondritic Nd isotope 524 compositions (Liégeois et al., 1998) while the signature of Tonian EFMC grains points 525 to a radiogenic source (Fig. 6). An East African provenance encompassing erosion 526 products from the Saharan Metacraton and the Arabian Nubian Shield is preferred for 527 several reasons. First, early Cryogenian to Tonian igneous rocks in these areas are typified by suprachondritic Nd–Hf isotope signatures, matching the detrital record of the 528 529 EFMC (Küster and Liégeois, 2001; Küster et al., 2008; Morag et al., 2011; Morag et al., 530 2012; Stern et al., 2010). Second, the sole fragments of late Stenian crust in north Gondwana have been described in the northern part of the Arabian Nubian Shield 531 532 (Be'eri-Shlevin et al., 2012) and could represent the source of EFMC late Stenian 533 zircon grains. Third, the zircon U-Pb-Hf systematics of recent detritus carried along by the Nile river strikingly resemble the Ediacaran detrital zircon record of the EFMC (Fig. **8d**) with two Neoproterozoic vertical arrays (550–650 and 950–1050 Ma), early Cryogenian to Tonian radiogenic detritus (650–950 Ma) and adequate (largely subchondritic) range of  $\epsilon$ Hf(t) for the Paleoproterozoic and Archean grains (Be'eri-Shlevin et al., 2014; lizuka et al., 2013). As the river largely drains the eastern part of the Sahara Metacraton and the Arabian Nubian Shield, we propose that the distal detritus that fed the EFMC Ediacaran basin was sourced from both of these crustal domains.

541

542 Constraining the relative proportions of proximal vs. distal supplies within the EFMC 543 basin has proven ambiguous. The 0.65–1.0 and older-than-1.8 Ga zircon populations 544 most likely originate from erosion of the Sahara Metacraton/Arabian Nubian Shield but 545 the case of 0.55–0.65 Ga grains is controversial as both the Cadomian arc and the Pan 546 African mobile belts represent adequate suppliers. Nonetheless in this case and as 547 shown above, the Cadomian arc can only contribute to the 0.58-0.61 Ga zircons since 548 magmatic activity in the Armorican Massif peaked at that time (Fig. 8b). Finally, variations in the proportions of 0.55-0.65, 0.65-1.0 and older-than-1.8 Ga grains 549 550 among EFMC metasediments (see section 5.2) possibly reflect temporal changes in 551 the Saharan Metacraton vs. Arabian Nubian Shield distal inputs. When Sahara 552 Metacraton supplies were dominant, Ediacaran detritus would have featured abundant 553 older-than-1.8 Ga grains (Meinhold et al., 2011), and led to a zircon U-Pb-Hf pattern 554 akin to sample TN46. In contrast, preferential erosion of the Arabian Nubian Shield would have delivered substantial amounts of 0.65–1.0 Ga grains (Morag et al., 2011; 555 Morag et al., 2012; Stern et al., 2010) and resulted in a pattern similar to that of sample 556 557 PdB16-01.

558

559 5.4 Crustal evolution of the EFMC and the North Gondwana margin

The Ediacaran (590-545 Ma) deposition of the Lower Gneiss Unit metasediments 561 562 stamps the formation of the earliest crustal rocks so far known in the EFMC. The nature (and even existence) of the basement on which the sediments were deposited 563 564 remains elusive as the EFMC crust segment typically lacks any remnant of pre-Neoproterozoic rocks, neither at surface level (Chelle-Michou et al., 2017; Melleton et 565 al., 2010; Padel et al., 2017; Roques et al., 1995) nor in the lower crustal xenoliths 566 sampled by Cenozoic volcanoes (Féménias et al., 2003; Rossi et al., 2006). 567 Examination of the detrital zircon U-Pb-Hf signature indicates that the Ediacaran 568 569 basins collected detritus from the adjacent Cadomian magmatic arc and distal sources from eastern Africa (see previous sections). Consequently, the EFMC crust segment 570 grew in the Ediacaran by pilling up pre-existing, eroded crustal materials of much 571 contrasted ancestries. From a crust evolution perspective, it is critical to establish the 572 573 relative proportions of eroded juvenile Neoproterozoic old VS. 574 Paleoproterozoic/Archean materials within the earliest EFMC crust as this would constrain in turn the mechanisms and extent of Neoproterozoic crust production along 575 576 the North Gondwana margin. Importantly, assessing the amount of young crust based 577 on the proportion of detrital zircon grains showing radiogenic Hf isotope signatures is 578 not relevant because: (i) the low zircon fertility of arc rocks and their tendency to show 579 concordant U-Pb dates (see Dickinson (2008); Moecher and Samson (2006)) 580 introduce sampling biases, and; (ii) grains showing unradiogenic Hf isotope signatures but crystallized from hybrid crust-mantle magmas may still encapsulate a juvenile 581 component diluted by the non-stoichiometric incorporation of ancient crustal Hf (Bolhar 582 et al., 2008; Couzinié et al., 2016; Kemp et al., 2006). This is likely the case of 583 unradiogenic Ediacaran-early Cryogenian grains from the EFMC (see section 5.3). 584

585

560

By contrast, S-type (meta)granites of the Velay Orthogneiss Formation may provide a 586 587 more reliable probe of the actual amount of Cadomian juvenile detritus within the Ediacaran basins. Following Couzinié et al. (2017), the (meta)granites indeed originate 588 589 from melting of the Ediacaran metasediments. These rocks show strikingly 590 homogeneous chondritic Hf isotope signatures, which resulted from dissolution of 591 detrital zircon grains and homogenization of their disparate Hf isotope signatures prior 592 to magma emplacement. If true, this model entails that the (meta)granites average the 593 Hf isotope composition of their Ediacaran sedimentary source. Earlier work pointed out 594 three main events of juvenile crust formation (i.e. with DM-like Hf-Nd isotope signatures) in the Gondwanian realm, in the Neoproterozoic (i.e. Cadomian and ANS-595 like, c. 0.65 Ga-old), Paleoproterozoic (Eburnean, c. 2.1 Ga-old) and Neoarchean (c. 596 597 2.8 Ga-old) (Gerdes and Zeh, 2006; Kemp et al., 2006; Linnemann et al., 2014; Orejana et al., 2015). Therefore, the Hf isotopic composition of the Ediacaran 598 599 sediments can be viewed as a mixture of those three components in different 600 proportions - in turn sampled by the Velay Orthogneiss Formation (meta)granites. Following this, the chondritic signature of the latter demands that 60-75 % of the 601 602 Ediacaran detritus in the EFMC corresponds to newly formed (i.e. <100 Ma-old) and isotopically juvenile Neoproterozoic crust (Fig. 10), either formerly part of the Cadomian 603 604 arc or originating from eastern Africa. This first-order estimate is minimal because 605 newly formed Neoproterozoic crust did not necessarily show a DM-like Hf isotope 606 composition. Several studies indeed documented that the very limited incorporation of 607 recycled crustal materials in the mantle source of arc and post-collisional magmas can 608 shift their Hf isotope composition towards non DM-like values (Nebel et al., 2011; 609 Roberts et al., 2012).

610

Interestingly, similar estimates can be obtained from the isotopic signature of several
late Ediacaran–early Paleozoic S-type granites from the North Gondwana margin, all

presumably derived from melting of Ediacaran sediments. In the Bohemian Massif, 613 614 magmatic zircons from the c. 540 Ma-old Laubach granite (Linnemann et al., 2014) show a tight range of  $\epsilon$ Hf(t) at 0 ± 2.4  $\epsilon$ -units (1 S.D.), identical to that of the Velay 615 Orthogneiss Formation (meta)granites. In the Iberian Massif, the Cambrian–Ordovician 616 617 volcano-plutonic Ollo de Sapo formation also displays an average  $\varepsilon$ Hf(t) of 0 ± 4.1  $\varepsilon$ units (1 S.D.) (Montero et al., 2017) whereas in both areas detrital zircons from 618 Ediacaran sediments feature a very wide range of  $\varepsilon$ Hf(t), spanning over 30 to 40  $\varepsilon$ -units 619 (Linnemann et al., 2014; Linnemann et al., 2017; Orejana et al., 2015). Such 620 observations further support the claim that late Ediacaran intra-arc or back-arc basins 621 developed along the North Gondwana margin largely represent newly formed 622 623 continental crust as they were primarily fed by detritus originating from <100 Ma-old, 624 Neoproterozoic terranes.

625

- 626 6. Conclusion
- 627

In this study, we demonstrate that the Lower Gneiss Unit of the eastern French Massif 628 Central, a portion of the internal (Moldanubian) zone of the late Paleozoic Variscan 629 630 collisional orogen, encompasses Ediacaran siliciclastic sedimentary successions 631 metamorphosed in the amphibolite-facies at Variscan times. Statistical analysis of 632 detrital zircon U-Pb date distributions reveals that the Lower Gneiss Unit crust segment had a distinct Ediacaran paleogeographic position with respect to adjacent 633 634 Variscan massifs (Central Iberian Zone, Bohemian Massif, Armorican Massif). Coupled zircon U-Pb-Hf systematics, notably the highly diverse Hf isotope composition 635 displayed by Ediacaran to late Cryogenian individual grains, can be reconciled with 636 Ediacaran detritus being collected from the adjacent Cadomian continental arc plus 637 additional hinterland supplies from eastern African sources (Sahara Metacraton and 638

Arabian Nubian Shield). A dominant proportion of the detritus (60-75% according to 639 our first-order, minimal estimates) represents fragments of Neoproterozoic crustal 640 641 materials extracted from the mantle shortly prior to erosion, transport and sedimentation in the Ediacaran basins of the EFMC. Therefore, even though 642 643 substantial amounts of genuine mantle-derived Neoproterozoic igneous rocks 644 experienced sedimentary reworking and were not preserved, their erosion products were collected in an (attenuated) crustal environment (the intra-arc or back-arc basins) 645 646 and became de facto long-term additions to the continental crust volume. Importantly, 647 the existence of concomitant sedimentary inputs from distal cratonic sources and the 648 incorporation of old crustal materials in continental arc magmas resulted in this newly 649 formed crust being intrinsically heterogeneous from an Hf isotope perspective. Several studies argued that a scatter in the zircon  $\varepsilon$ Hf(t) at a given time period, as observed in 650 651 the Ediacaran-Cryogenian record of the North Gondwana margin, reflects the dominance of crust reworking processes (Dhuime et al., 2017; Kemp et al., 2006; 652 653 Vervoort and Kemp, 2016). In contrast, this work shows that such a situation may just 654 as well reflect voluminous new crust production.

655

#### 656 Acknowledgements

657

C. Guilbaud made the thin sections; J.-M. Hénot assisted during SEM imaging; M.
Ballèvre provided the file of Fig. 1; M. Mintrone contributed to Fig. 2; A. Laurent, A.
Vezinet, A. Villaros, V. Gardien and G. Mahéo participated to stimulating discussions;
C. Storey, U. Linnemann and an anonymous reviewer substantially improved the
manuscript; may they all be thanked.

Figure 2: Geological map of the Velay dome area showing the location of analyzed metasediments. The extent of Variscan partial melting of the metamorphic lithologies is not shown for sake of clarity. Redrawn after Ledru et al. (2001) and regional geological maps of France at scale 1/50000.

684

Figure 3: Representative cathodoluminescence images of zircon grains from Lower
Gneiss Unit metasediments. The locations of laser spots (white and yellow circles for
U-Pb and Lu-Hf analyses respectively) are indicated along with the spot name (zXX or
#YY). The corresponding <sup>206</sup>Pb/<sup>238</sup>U dates (if <1.2 Ga) or <sup>207</sup>Pb/<sup>206</sup>Pb dates (if >1.2 Ga)
are quoted with 2σ uncertainty, in Ma. All displayed analyses are concordant at >95%.

690 Hf isotope data are reported using the  $\epsilon$ Hf calculated at the <sup>206</sup>Pb/<sup>238</sup>U or <sup>207</sup>Pb/<sup>206</sup>Pb 691 date obtained on the same zircon domain, quoted with 2 $\sigma$  uncertainty.

692

Figure 4: Tera–Wasserburg diagrams ( $^{238}U/^{206}Pb$  vs.  $^{207}Pb/^{206}Pb$ ) showing Neoproterozoic zircon data for the Lower Gneiss Unit metasediments. Error ellipses/ages are quoted at 2 $\sigma$  level of uncertainty. Colored ellipses are those included in Concordia age calculations. Dotted ellipses for TN46 refer to data from Chelle-Michou et al. (2017).

698

Figure 5: Zircon U–Pb date distribution of investigated metasediments from the Lower Gneiss Unit represented as Kernel Density Estimates (KDE). Only 95–105% concordant <sup>206</sup>Pb/<sup>238</sup>U (for dates < 1.2 Ga) and <sup>207</sup>Pb/<sup>206</sup>Pb dates (for dates > 1.2 Ga) were considered. Circles below the x-axis are the central value of individual data points. Plotted with the DensityPlotter program of Vermeesch (2012) using an adaptive bandwidth.

705

Figure 6: Combined U-Pb and Lu-Hf isotopic data for zircons from Ediacaran metasediments, constituent rocks of the Lower Gneiss Unit in the Eastern French Massif Central. The data for sample TN46 are from Chelle-Michou et al. (2017). The  $\epsilon$ Hf(t) range for the Depleted Mantle reservoir is bracketed by the models of Naeraa et al. (2012) and Griffin et al. (2002). The dotted arrow represents the isotopic evolution of continental crust (calculated using an average crustal <sup>176</sup>Lu/<sup>177</sup>Hf ratio of 0.0113).

712

Figure 7: (a) Non-metric multi-dimensional scaling plot of the Ediacaran–Lower Cambrian (meta)sedimentary dataset comprising 54 samples from several zones of the Variscan belt. Samples from the Ossa-Morena zone (n=2) are not depicted for sake of clarity. See section 5.3 for details on the calculations. (b) Same plot on which the zircon

U–Pb date distributions of four selected samples from the literature are displayed with
the aim to highlight the end-member zircon populations.

719

720 Figure 8: (a-b) Available intrusion ages for igneous rocks older than 550 Ma in the 721 northern Armorican Massif compared to the detrital zircon record of the Lower Gneiss 722 Unit in the Eastern French Massif Central, represented as Kernel Density Estimates (KDE). Only 95–105% concordant  $^{206}$ Pb/ $^{238}$ U (for dates < 1.2 Ga) and  $^{207}$ Pb  $^{206}$ Pb dates 723 (for dates > 1.2 Ga) were considered. Plotted with the DensityPlotter program of 724 725 Vermeesch (2012) with an adaptive bandwidth. Geochronological data for the Armorican Massif were extracted from the compilation of Thiéblemont et al. (2017) 726 supplemented by results from Inglis et al. (2005); Inglis et al. (2004) and Vidal (1980). 727 728 (c) Hf isotope signature of igneous rocks from the northern Armorican Massif (from Hf isotope studies or recalculated from Nd isotopes based on the relation  $\varepsilon Hf(t) = 1.36$ 729 730  $\epsilon Nd(t) + 3$  determined by Vervoort et al. (1999)) compared to the detrital zircon record 731 of the EFMC. Data from D'Lemos and Brown (1993); Dabard et al. (1996); Guerrot 732 (1989); Samson and D'Lemos (1998); Samson et al. (2003). (d) U-Pb/Lu-Hf 733 systematics of detrital zircon grains from recent sediments of the Nile River, taken as 734 representative of the eastern part of the Sahara Metacraton and western part of the 735 Arabian Nubian Shield, compared to the EFMC record. Data from Be'eri-Shlevin et al. 736 (2014) and lizuka et al. (2013).

737

Figure 9: Geological sketch of the northern part of the Gondwana by the late Ediacaran (c. 560 Ma) delineating the main crustal domains (age and Nd–Hf isotope signature) representing putative zircons sources for the EFMC detritus. Arrows represent the likely sources of the detrital supply that fed the Ediacaran EFMC basin. Inspired from Garfunkel (2015) and references therein.

Figure 10: Triangular diagram showing EHf(545 Ma) of a virtual sedimentary material as 744 a function of the relative proportions of juvenile Neoproterozoic (Cadomian and ANS-745 like), Paleoproterozoic (Eburnean) and Neoarchean crust in the latter, assuming 746 747 identical Hf concentrations in the three end-members. The EHf(545 Ma) of each component was calculated based on a <sup>176</sup>Lu/<sup>177</sup>Hf of 0.0113 and extraction from a DM 748 749 source (considering the average value of the models from Griffin et al. (2002) and 750 Naeraa et al. (2012)). The highlighted value of zero corresponds to the average composition of the Ediacaran metasediments required to explain the zircon Hf isotope 751 752 signature of the Velay Orthogneiss Formation (and other pre-Variscan granitoids 753 emplaced at the Ediacaran-Cambrian boundary, see text for details).
