18 **Abstract**

19 Radon ( $^{222}\text{Rn}$ ) activity in air was measured for about six months at the summit of Mt. Etna Central  
20 Crater (Sicily) by integrative radon dosimetry at two different heights above ground level (5 cm and 1  
21 m). This technique for air radon monitoring proved operational in the harsh volcanic environment of  
22 Mt. Etna summit with a 94% recovery rate of dosimeters. In the South-East sector exposed to the main  
23 gas plume, mean radon activity in free air (height 1 m) is significantly higher than the local background  
24 and the ground level activity (height 5 cm). The results strongly suggest that the plume is enriched in  
25 radon by  $\approx 550 \text{ Bq/m}^3$ , which has never been evidenced before. Radon activities also reflect soil  
26 degassing occurring in the proximity of the crater, with increased ground level activities in zones of  
27 enhanced soil fracturing and degassing. Radon measurements also revealed a hotspot in front of the  
28 Voragine vent with extraordinary high levels of air activities ( $26 \text{ kBq/m}^3$  at ground level and  $8 \text{ kBq/m}^3$   
29 in free air). The temporal variation of radon activity was investigated by replacing a few stations half  
30 way through the exposure period. The only significant increase was associated with the site located  
31 under the main gas plume and correlated with eruptive unrest within the crater. Finally, air radon  
32 levels higher than the recommended threshold of  $300 \text{ Bq/m}^3$  were detected in several zones on the  
33 rim and could generate a non-negligible radiologic dose for workers on the volcano.

36

37

38 **1) Introduction**

39 **[1]** Radon ( $^{222}\text{Rn}$ ) is a radioactive noble gas produced by the decay of  $^{226}\text{Ra}$ . As such, radon abundance  
40 is generally high in U-bearing geological formations, including volcanic and geothermal zones (e.g.,  
41 Monnin, 2001). Since the pioneering work of Chirkov at Karymsky volcano, Kamchatka (Chirkov, 1975),  
42 radon measurements at active volcanoes, either in fumaroles or in soil gases, have been carried out  
43 worldwide in order to investigate radon activity variations as a precursory monitoring tool (see recent  
44 reviews by Cigolini et al., 2016 and Morales-Simfors et al., 2020, and references therein). Albeit  
45 promising, the radon signature in soil gases and/or fumarolic discharges appears however not always  
46 easy to decipher. Besides the well-known diurnal and seasonal variation of radon emissions related to  
47 meteorological effects and earth tides, radon activities can indeed be affected by local variations of  
48 soil temperature and humidity, local stress regime constraints and other parameters which may hide  
49 the signature of magmatic processes at depth (Zimmer and Erzinger, 2003; Cigolini et al., 2016; Mollo  
50 et al., 2018).

51 **[2]** The primary magmatic vapor released in gaseous plumes at open-conduit degassing volcanoes thus  
52 could be an ideal candidate to investigate radon anomalies directly linked to magmatic processes at  
53 depth. Unfortunately, almost no systematic survey of in-air radon activities in volcanic plumes have  
54 been carried out so far, apart from a single study on short-lived  $^{222}\text{Rn}$  daughters at Mount Erebus,  
55 Antarctica (Polian and Lambert, 1979). In marked contrast, emissions of the last three radon daughters  
56 (namely  $^{210}\text{Pb}$ ,  $^{210}\text{Bi}$  and  $^{210}\text{Po}$ ) in volcanic plumes have been well established for more than 40 years  
57 (e.g., Lambert et al., 1976). The study of  $^{210}\text{Pb}$ - $^{210}\text{Bi}$ - $^{210}\text{Po}$  radioactive disequilibria in magmatic gases

58 has proved efficient to infer degassing dynamics of active volcanic systems, either in a state of open-  
59 conduit persistent degassing (Lambert et al., 1985; Gauthier et al., 2000; Le Cloarec and Pennisi, 2001;  
60 Allard et al., 2016), in an eruptive dome setting (Le Cloarec and Gauthier, 2003) or during lateral fissure  
61 eruptions (Gauthier et al., 2016).

62 **[3]** Early experiments by Sato et al. (1980) suggested that radon is thoroughly degassed from liquid  
63 silicates at magmatic temperatures, a finding later confirmed by radon analyses of freshly erupted  
64 lavas (Gill et al., 1985). However, an experimental investigation of radon diffusion in andesitic melts  
65 (Gauthier et al., 1999) suggested that complete radon degassing is achieved only when major gas  
66 species (mostly CO<sub>2</sub> and H<sub>2</sub>O) act as a radon carrier. Indirect evidence of sustained radon degassing  
67 from erupting magmas can be found in the observation of large <sup>210</sup>Pb deficits over <sup>226</sup>Ra in some recent  
68 lavas (e.g., Gauthier and Condomines, 1999; Berlo et al., 2006). Meanwhile, <sup>210</sup>Pb excesses over <sup>226</sup>Ra  
69 have been observed elsewhere suggesting the reverse behavior, that is radon accumulation at depth  
70 followed by its subsequent radioactive decay within the magma (e.g., Berlo et al., 2006; Condomines  
71 et al., 2010; Sigmarsson et al., 2015). The question whether radon is efficiently released through  
72 outgassing of magmatic volatiles at volcanic craters or decays out at depth, due to its relatively short  
73 half-life of 3.8 days, remains largely unanswered because magmatic plume emissions of radon have  
74 not yet been documented.

75 **[4]** In May 2018, we installed a network of radon passive dosimeters all around the rim of Mt. Etna  
76 Central Crater, in Sicily. The dosimeters were left on site for about five months (from May 24, 2018 to  
77 October 11, 2018), until their retrieval for the laboratory determination of radon activity. The first goal

78 of the study was to determine mean radon levels in the air around the crater in order to constrain  
79 radon emissions related to volcanic plume, fumaroles, high soil degassing, or a combination of these  
80 various sources. The second goal of the study was to test the capability of radon measurements in air  
81 to be part of the monitoring system of active volcanoes, Mt. Etna being one of the best monitored  
82 volcano laboratory in the world (Bonaccorso et al., 2004). Finally, this study was also aimed at  
83 assessing the potential radiologic hazard associated to high radon levels in air around the crater, since  
84 Mt. Etna summit is systematically visited every year by thousands of tourists, scientists and  
85 volcanological guides, and health hazards related to volcanic gas plumes are often pointed out  
86 (Delmelle et al., 2002; Hansell and Oppenheimer, 2004).

## 87 **2) Area of study**

88 **[5]** Mt. Etna is a stratovolcano located on the east coast of Sicily and one of the most active volcanoes  
89 in Europe. Its edifice is a 3300 m above sea level (a.s.l.) high cone with a collapsed eastern flank (Valle  
90 del Bove) and a complex summit morphology (e.g., Neri et al., 2017) composed of three different  
91 groups of active craters (see Figures 1 and 2): (i) the Central Crater (CC) hosting two inner craters  
92 named Bocca Nuova (BN) and Voragine (VOR), (ii) the North-East Crater (NEC), and (iii) the South-East  
93 Craters. Its present eruptive activity is characterized by diverse eruptive styles, from purely effusive to  
94 mild and violent strombolian with very energetic lava fountains (e.g., Allard et al., 2016). In addition,  
95 Mt. Etna is often classified as an open-conduit volcano because of the continuous emission of large  
96 quantities of magmatic gases from its main craters (Aiuppa et al., 2008; Salerno et al., 2009a). An active  
97 hydrothermal system is also located at shallow depth beneath its summit (Liotta et al., 2010).

98 **[6]** This study focused on the Central Crater because persistent passive or active plume emissions from  
99 Bocca Nuova and Voragine vents ensured an almost continuous presence of magmatic gases on the  
100 crater rim, whereas other craters were mostly emitting gas through fumarole fields. The degassing  
101 regime of the Central Crater between May and October 2018 reflects the recent eruptive activity:

102 - (i) BN and VOR craters merged after the December 2015 and May 2016 paroxysmal eruptions and  
103 eruptive products totally filled the two craters (Corsaro et al., 2017; Marchese et al., 2018).  
104 Subsequently, the tectonic structure of the summit was considerably modified and a swarm of North-  
105 South oriented fractures opened from the North-East Crater to the South-East Craters, passing east of  
106 the Central Crater (Fig. 1a; see also Marchese et al., 2018). It led to both enhanced fumarolic activity  
107 and increased diffuse soil degassing within the Central Crater and around it (see for instance Figure 3  
108 in Marchese et al., 2018). Our field observations suggest that this degassing activity was still present,  
109 albeit at lower intensity, in 2018 at the time of the study.

110 - (ii) Since May 2016, BN and VOR craters have been subsiding, progressively reforming the former  
111 geometry of the Central Crater. In August 2016, a degassing pit opened on the inner east flank of VOR  
112 crater twenty meters below the rim (Marchese et al., 2018; VOR vent, see Figures 1 and 2), apparently  
113 draining most of diffuse emissions nearby and remained active in 2018 at the time of our  
114 measurements. In early 2018, a new degassing pit opened on the west side of BN crater floor (BN1,  
115 see Figures 1 and 2), where most of the degassing activity took place.

116 - (iii) In late May/early June 2018, at the start of the experiment, activity mostly consisted in sustained  
117 degassing from the BN1 vent, and additional mild degassing at the NE Crater (Figure 2). In the course

118 of summer 2018, a slight unrest occurred in the eruptive activity as witnessed by thermal anomalies  
119 observed from the Sentinel imager satellite (Figure 2) and other remote sensing approaches (Marchese  
120 et al., 2019), as well as an increase in SO<sub>2</sub> fluxes (see Supplementary Material) and volcanic tremor  
121 (e.g., *Bollettino settimanale sul monitoraggio vulcanico, geochimico e sismico del vulcano Etna,*  
122 *20/08/2018 - 26/08/2018*, 2018). Magmatic explosions were further reported by witnesses at BN  
123 (explosion bangs and visual observations of volcanic bombs ejected from the craters), this unrest  
124 period culminating in the opening of a new vent on the east side of the BN crater (BN2, see Figures 1  
125 and 2) in August 2018 (see Figure 4 in Marchese et al., 2019).

126 [7] Beside the activity at Central Crater, major eruptive events during the 2016-2018 period included  
127 a sequence of six effusive eruptions at South East Craters in February-March 2017 (De Beni et al.,  
128 2019), a short strombolian and effusive episode at New South East Crater by late August 2018 and a  
129 lateral fissure eruption in December 2018 (De Novellis et al., 2019).

### 130 **3) Methods**

131 [8] A temporary network of radon passive dosimeters was deployed for five months (from May to  
132 October 2018) around the Central Crater of Etna and in the close vicinity of the summit area in order  
133 to assess radon levels at Mt. Etna summit. The network initially consisted in 29 monitoring stations set  
134 on the Central Crater rim (yellow and purple dots in Figure 1a) and 3 reference stations at distance  
135 from the summit area (La Montagnola, Pizzi Deneri, Torre del Filosofo, Fig. 1b). An example of radon  
136 station is shown in Figure 3. It consists of two dosimeters (one at ground level - i.e., 5 cm above ground  
137 - and one in free air - i.e., at 1 m elevation) fixed to a 1.5 m high wooden stick solidly anchored to the

138 ground. This configuration was chosen in order to discriminate the contribution of soil radon emissions  
139 from that of plume radon emissions. The bottom dosimeter would indeed mostly reveal the intensity  
140 of very local soil emissions while the top dosimeter will also be sensitive to radon from further distant  
141 sources and transported by the wind (such as degassing vents). In July 2018, dosimeters at five  
142 monitoring stations were picked up for analysis and immediately replaced by new dosimeters.  
143 Additionally, a fourth reference station was installed further from the summit area, down in the Valle  
144 del Bove (Fig 1b). As a whole, no less than 76 passive dosimeters were used for this experiment.

145 **[9]** For this experiment, we used DPR2 dosimeters provided by the Algade company (Bessines-sur-  
146 Gartempe, France). These dosimeters are made of a LR-115 (cellulose nitrate) sensitive film,  
147 encapsulated in a sealed plastic half-dome in order to prevent both thoron ( $^{220}\text{Rn}$ ) and radioactive  
148 aerosol particles from contributing to the measurement. The Algade company indicates a minimum  
149 exposure period of two months (indoor conditions) in order to properly measure a radon activity of  
150 about  $20 \text{ Bq/m}^3$ . Although LR-115 films had been previously used to measure in-soil radon activities on  
151 volcanoes (e.g., Seidel and Monnin, 1984), they were used for the first time in outdoor conditions on  
152 a volcano during the present study. It was thus decided to leave dosimeters in the field for the whole  
153 summer period (May 24 – October 11) in order to ensure sufficient radon exposure. Nonetheless, five  
154 crater stations were replaced on the 6<sup>th</sup> of July 2018 with several objectives: (i) validate the  
155 methodology by checking that cellulose nitrate films were not corroded by acid gases and damaged by  
156 moisture, (ii) check the exposure level after two months in order to avoid film saturation and (iii) look  
157 for potential temporal variations between May-July and July-October 2018. After collection of the  
158 passive dosimeters in the field, they were sent to the Algade laboratory (within two days) where the

159 films were analyzed (see previous studies using LR-115 films for further methodological and analytical  
160 details; e.g., Seidel and Monnin, 1984). Radon activities were obtained within two weeks, with a global  
161  $2\sigma$  uncertainty (counting statistics, calibration error, error due to temperature variations during the  
162 chemical processing of the dosimeter, error coming from the slightly variable quality of the sensitive  
163 films).

164 **[10]** Because passive dosimetry integrates radon activity in air over a long period of time (weeks to  
165 months), it filters out the large variability of radon activity in air due to short-period (< 1 day)  
166 fluctuations, often inherited from meteorological fluctuations (e.g. Zimmer and Erzinger, 2003). As  
167 such, it is an easy-to-deploy and low-cost technics allowing determination of a mean value  
168 representative of radon emission and accumulation at a given place over a given time period.  
169 Moreover, a dosimeter does neither require a power supply nor data logging system and it can be  
170 installed for several months even in harsh outdoor conditions without damage.

171 **[11]** In order to identify the zone under volcanic plume influence, wind direction and intensity over  
172 the crater during the experiment period, May to October 2018, are needed. We used open-access data  
173 acquired by radiosondes launched twice a day at Trapani in western Sicily  
174 (<http://weather.uwyo.edu/upperair/sounding.html>). Wind direction and horizontal wind speed were  
175 obtained from each radiosonde profile, selecting the values measured in the range of elevation of Mt.  
176 Etna summit craters (between 3000 and 3400 meters a.s.l.). Although radiosonde data refer to a site  
177 located 220 km away from Mt. Etna, high-altitude winds are relatively stable over long distances,  
178 especially when there is no obstacle from the terrain in between, as it is the case of Sicily where no

179 3000m-high mountains exist apart from Mt. Etna. Trapani data are thus a good proxy for Mt. Etna high-  
180 altitude wind-field, as evidenced in other studies on Mt. Etna's plume (e.g., Scollo et al., 2014).

#### 181 **4) Results**

182 **[12]** Out of 76 installed dosimeters, only three were missing at the end of the experiment. All films but  
183 one could be analyzed and did not present any sign of acid degradation. A single pair of dosimeters  
184 was clogged into a cm-thick crust of soldered dust and therefore excluded from the dataset as it was  
185 impossible to determine if radon could still enter the capsule. We finally obtained a global recovery  
186 rate of 94% (number of interpretable dosimeters/number of installed dosimeters). This demonstrates  
187 that passive dosimetry is a technique suitable for harsh outdoor volcanic conditions (windy, cold,  
188 humid and acid atmosphere).

##### 189 *4.1 Spatial distribution of radon anomalies*

190 **[13]** All results and station details are given in Table 1. The overall uncertainty on obtained  $^{222}\text{Rn}$   
191 activities varies between 14% and 38% with a mean value of 22% ( $2\sigma$  relative uncertainty). Reference  
192 stations located far from the active crater zone (see Figure 1b) present a mean activity of  $63 \pm 18 \text{ Bq/m}^3$   
193 at ground level and a mean activity of  $36 \pm 9 \text{ Bq/m}^3$  at a meter above the ground (free air). Higher  
194 values near the ground are not surprising because the only source of radon far from degassing vents  
195 is soil degassing. The activity found in free air is in qualitative agreement with previous radon  
196 measurements in the outdoor air of Mt. Etna region, ranging from 3 to  $20 \text{ Bq/m}^3$  (Vaupotič et al., 2010).

197 **[14]** Radon activities measured on the crater rim are characterized by a high variability: ground level  
198 activities are found in the range 40 -  $26,000 \text{ Bq/m}^3$ , while free air activities range from 37 to 8800

199 Bq/m<sup>3</sup>. Despite these wide ranges of values, geographical patterns can be observed. Figures 4a and 4b  
200 represent the spatial distribution of integrated ground-level and free-air radon activities measured at  
201 each station in the main four sectors of the crater rim (North-West, North-East, South-East and South-  
202 West), as well as the wind directions during the exposure period. The main wind direction is from NW  
203 to SE with an occurrence percentage > 80%. It is noteworthy that the NW sector presents the lowest  
204 ground-level and free-air activities among those recorded all around the crater. In this sector, mean  
205 activity at ground level ( $82 \pm 17$  Bq/m<sup>3</sup>) is in agreement with the respective mean background activity  
206 measured at reference stations ( $63 \pm 18$  Bq/m<sup>3</sup>) while mean activity in free air ( $71 \pm 13$  Bq/m<sup>3</sup>) is slightly  
207 higher than reference stations mean value ( $36 \pm 9$  Bq/m<sup>3</sup>). No statistical difference between the two  
208 elevations is found, even though the mean ground-level activity is slightly higher than the mean free-  
209 air activity. Both NE and SW sectors show a very similar pattern with significantly higher ground-level  
210 activities ( $155 \pm 43$  and  $186 \pm 62$  Bq/m<sup>3</sup>, respectively) but low free-air activities ( $75 \pm 10$  and  $90 \pm 15$   
211 Bq/m<sup>3</sup>, respectively) similar to those in the NW sector. Finally, the SE sector presents the highest mean  
212 values of both ground-level and free-air activity with mean free-air activity ( $704 \pm 409$  Bq/m<sup>3</sup>) markedly  
213 higher than mean ground-level activity ( $301 \pm 114$  Bq/m<sup>3</sup>). This latter pattern implies the contribution  
214 of an external radon source (i.e., different from soil degassing) transported by the wind. Since the two  
215 main degassing vents of Bocca Nuova (BN1 and BN2) and the SE sector of the crater rim are aligned  
216 along the main wind direction, these results strongly suggest that the observed radon anomaly might  
217 be associated with the gas plume released by BN. This observation is the first direct evidence that  
218 magmatic gases released in the main crater plume of Mt. Etna are significantly enriched in radon.

219 **[15]** Ground-level radon anomalies observed both in the SW and NE sectors of the crater rim are  
220 coherent with the degassing phenomenology observed in the field. The SW sector of Mt. Etna's Central  
221 Crater mostly consists of a terrace covered by a massively altered yellow soil that likely results from  
222 the chemical alteration of basaltic rocks by acidic soil gases. The NE sector is a highly fractured zone  
223 (Marchese et al., 2018; see also Figure 1a) that also presents many features of severe soil alteration.  
224 Both sectors are sites of elevated soil CO<sub>2</sub> diffuse degassing (Giammanco et al., 2016) that is likely  
225 associated with important radon soil emanations that can produce a significant radon anomaly at  
226 ground level. They are also areas of intense fumarolic activity as witnessed by the water vapor intensity  
227 seen in Sentinel images (see Figure 2). In marked contrast, important diffuse or fumarole degassing  
228 was not observed in the NW sector, which is in agreement with the low levels of radon activity  
229 measured close to ambient background.

230 **[16]** A hotspot of anomalous radon emission was also identified near the Voragine degassing vent (at  
231 the station located twenty meters upslope of the vent, see Figure 1a). At ground level, radon activity  
232 reaches 26,000 Bq/m<sup>3</sup> whereas at 1 m height, it is 8,800 Bq/m<sup>3</sup>. No equivalent activity levels were  
233 found elsewhere around the crater including at stations adjacent to the hotspot site, and no  
234 progressive increase of radon activity towards it can be observed. It suggests that the hotspot is due  
235 to a very localized and peculiar structure, likely related to the strong degassing from the Voragine vent.  
236 In any case, this station was excluded from the computation of the sector mean radon activity.

237 *4.2 Temporal evolution of radon anomalies*

238 **[17]** Figure 5 represents, for each of the four sectors around the Central Crater (Fig. 5a to 5d), the  
239 temporal evolution of radon activity at stations that were retrieved and immediately replaced in July  
240 2018. Coherent patterns between the two periods of exposure can be observed for the different  
241 sectors, although only one pair of dosimeters (ground-level and free-air) has been collected and  
242 analyzed from each sector. For the two northern sector stations (NW and NE), free-air integrated radon  
243 activities decreased (NW) or increased (NE) by a factor of  $\sim 2$  during the second period of exposure but  
244 remained within the range of reference values, in agreement with the hypothesis of limited influence  
245 of the gas plume. Ground-level activities increased by a factor of  $\sim 3$  in both cases and exhibit values  
246 significantly higher than the reference level (Fig. 5a and 5b). This pattern could be tentatively  
247 interpreted as resulting from enhanced soil degassing during the second period although a  
248 meteorological effect, for instance due to an increased stability of the surface air layer, cannot be  
249 ruled out. The two southern sector stations (SW and SE) are both characterized by a decrease in radon  
250 activity at ground-level between the two periods (by a factor of  $\sim 2$ ), hence producing values at the  
251 reference level (Fig. 5c and 5d). In marked contrast, free-air radon activities are significantly higher and  
252 above the reference value, which is especially obvious for the SE station where radon activity at 1 m  
253 above ground level is 15 times higher than during the first period of exposure. Such decoupling  
254 between ground-level and free-air activities excludes any interpretation based on a modification of  
255 the local soil radon flux (either from meteorological or volcanological origin). In which case, an even  
256 more important increase of ground-level activity should have been observed too. In fumaroles,  
257 rainfalls can trigger positive radon anomalies but such induced radon enrichments usually are of much  
258 lower magnitude (Zimmer and Erzinger, 2003). Furthermore, weather conditions during the whole

259 period of the experiment were rather calm, with rare rainy events evenly distributed at the end of the  
260 spring season and the beginning of the fall season. Since both wind direction and speed were similar  
261 during May-Jul and Jul-Oct periods (see Fig. 5e and 5f), it can thus be suggested that the tremendous  
262 increase in free-air radon activity observed at the SE station is related to the volcanic plume itself,  
263 especially because this station was installed in the windiest part of the SE sector (Fig. 4), downwind  
264 the active Bocca Nuova vents. Although sustained degassing activity occurred throughout the study  
265 period, it is worth noting that several signs of volcanic unrest were noticed, starting mid-July 2018 right  
266 after the new sets of dosimeters were installed around the crater rim. Evidences for this unrest may  
267 be found in the occurrence of strombolian explosions within the Central Crater (see also section 2 and  
268 Marchese et al., 2019), increasing thermal anomalies (Fig. 2), increasing SO<sub>2</sub> fluxes (see Supplementary  
269 Material) and higher tremor with noticeable excursions into the red alert zone (e.g., *Bollettino*  
270 *settimanale sul monitoraggio vulcanico, geochimico e sismico del vulcano Etna*, 20/08/2018 -  
271 26/08/2018, 2018). It thus suggests a correlation between stronger magmatic activity at the summit  
272 craters and increased radon activity in the air (and possibly also at the ground level) at the summit  
273 area of the volcano (see discussion hereafter).

## 274 **5) Discussion**

### 275 *5.1 Radon enrichments in Mt. Etna gas plume*

276 **[18]** In each summit sector of the volcano where the plume contribution is low or even virtually  
277 negligible (reference stations, NW, NE (including the Voragine hotspot) and SW sectors), the ratio of  
278 free-air to ground-level radon activities (termed hereafter air-soil ratio) range from  $0.33 \pm 0.23$  to 0.86

279  $\pm 0.37$ , with an average value of  $0.53 \pm 0.20$ . In marked contrast, the air-soil ratio in the SE sector  
280 averages  $2.34 \pm 0.85$ . Together with the high mean free-air activity observed in the same sector, this  
281 suggests a significant radon enrichment in the crater plume compared to the atmospheric background,  
282 in agreement with a theoretical model that proposed high plume emissions of radon from open-  
283 conduit volcanoes due to the persistent regeneration of radon in the degassing reservoir at depth by  
284 the decay of non-volatile  $^{226}\text{Ra}$  (Terray et al., 2018). In order to quantify this enrichment, the local  
285 contribution of soil degassing must be taken into account and subtracted. To do so, we assume that  
286 the air-soil ratio of  $0.53 \pm 20$  represents the typical vertical gradient of radon activity in air from soil  
287 degassing in the absence of external aerial sources, which is in qualitative agreement with 1D vertical  
288 turbulent diffusion models (Jacobi and André, 1963). It can be tentatively assumed that such a vertical  
289 gradient also applies to the SE sector of Mt. Etna Central Crater. Therefore, it is possible to compute  
290 that the contribution from radon soil emanation at 1 m above ground level is  $0.53 \times 301$  (mean ground  
291 level activity) =  $160 \text{ Bq/m}^3$ . Considering the average free air radon activity for the SE sector ( $704 \text{ Bq/m}^3$ ,  
292 Table 1), this leads to a radon enrichment in the plume of  $704 - 160 \approx 550 \text{ Bq/m}^3$ .

293 **[19]** This figure is the first direct estimate of radon activity in a gas plume released by an open-conduit  
294 volcano. Nonetheless, a previous study on Mount Erebus (Polian and Lambert, 1979) dealt with plume  
295 activities of aerosol-attached  $^{218}\text{Po}$  (the first daughter of  $^{222}\text{Rn}$ ) in the range  $170\text{-}586 \text{ pCi/m}^3$  ( $6.3\text{-}21.7$   
296  $\text{Bq/m}^3$ ). The comparison of these two estimates is not straightforward since significant radioactive  
297 disequilibria prevail between radon and its first daughter in the lower atmosphere ( $(^{218}\text{Po}/^{222}\text{Rn})$   
298 activity ratio as low as 0.45 during summertime, e.g. Kojima, 1996). Furthermore, a significant fraction  
299 of  $^{218}\text{Po}$  atoms is not attached to aerosol particles and cannot be sampled by standard filtration

300 methods (Tokonami et al., 1996), this fraction of unattached atoms being preponderant in water-  
301 saturated atmospheres like volcanic plumes. Accordingly, the estimate proposed by Polian and  
302 Lambert (1979) must be regarded as a minimum value. Conversely, our estimate of radon activity in  
303 the volcanic plume is one order of magnitude lower than that measured in mid-temperature fumarole  
304 discharges from VOR Crater (Giammanco et al., 2007). Because many fumaroles are located on the  
305 inner walls of the Central Crater and along the fracture swarm extending from North-East Crater to  
306 South-East Craters (Figure 1a), it cannot be ruled out that they contributed to the radon activity  
307 measured by our monitoring stations. This contribution however, likely remains moderate since active  
308 fissures in the SE sector are mostly located downslope the summit flank (Fig. 1a), so that dominant  
309 winds blow fumarolic gases away from our monitoring stations. Whatever be this contribution, the  
310 value of 550 Bq/m<sup>3</sup> for the bulk volcanic plume in the SE sector thus should be regarded as a maximum  
311 estimate, albeit realistic.

## 312 *5.2 Spatial variability of radon activity and degassing pathways*

313 **[20]** As previously discussed and apart from the Voragine hotspot, the highest radon activities were  
314 measured in the SE sector of the Central Crater, which is the most exposed area to the volcanic plume  
315 during the study period. Looking into more details, a significant variability of free-air radon activities is  
316 observed in this sector (Table 1). The three southernmost stations in the SE sector show relatively  
317 medium to high values (in the range 80-222 Bq/m<sup>3</sup>) whereas the two northernmost stations measured  
318 up to 2500 Bq/m<sup>3</sup>, the highest value recorded in free-air at the summit of Mt. Etna, with the exception  
319 of the VOR hotspot. These two latter stations were located not only in the windiest subsector of the

320 SE sector (Fig. 4b), but also the closest to the BN2 vent, a few tens of meters downwind. Furthermore,  
321 passive dosimeters at one of these two stations were retrieved in July 2018 and immediately replaced  
322 by new ones. While radon activity at this station remained moderate between May and July ( $73 \pm 20$   
323  $\text{Bq/m}^3$ ), a sharp increase was noticed for the second period, peaking at  $1091 \text{ Bq/m}^3$ . Interestingly, the  
324 BN2 vent opened and started to be active on August 16, 2018, which implies that the gas released from  
325 the new vent could be associated with the observed radon increase during the second period of  
326 exposure. This could be due either to a lower dilution of the gas plume arising from BN2, or to a higher  
327 content of radon in the gas discharge from the new BN2 vent. No matter what scenario applies best,  
328 these results suggest that a change in the degassing process – through the opening of a new vent –  
329 can be tracked through radon monitoring in air.

330 **[21]** The situation is rather different for the Voragine hotspot, where the highest radon activity is found  
331 at ground level. At this station, free-air radon activity could merely result from the vertical gradient of  
332 radon diffusion from soil to air at 1 meter above ground level (air-soil ratio of 0.33). The high radon  
333 activity at this place, thus, does not necessarily implies that the plume issued from VOR vent was  
334 particularly enriched in radon. Nevertheless, extremely high radon activities next to the VOR vent are  
335 not puzzling, even at ground level. This vent formed in August 2016 in a zone that was highly fractured  
336 by the 2015-2016 paroxysmal episodes at Voragine Crater. Before the vent opening, those fractures  
337 served as main pathways for soil gas emissions and fumarole discharges while the main degassing vents  
338 within the Voragine were still plugged (Marchese et al., 2018). When the radon monitoring station was  
339 installed in 2018, we measured a soil temperature of  $360^\circ\text{C}$  at a depth of 30 cm with a Type K  
340 thermocouple placed within one sealed crack on the eastern rim of Voragine, just nearby the station

341 that recorded the radon hotspot. Therefore we propose that the fissure swarm on the eastern rim of  
342 Voragine was one of the most permeable part of the crater structure, allowing deep gas ascent, as  
343 suggested for a previous eruptive cycle (Giammanco et al., 2007).

### 344 *5.3 Temporal variability of radon activities as a tool for volcano monitoring?*

345 **[22]** As shown in Figures 5a to 5d, a marked temporal evolution between the two exposure periods in  
346 each sector of the volcano was observed. While ground-level emissions of radon appear slightly higher  
347 during the second period on the northern side of Central Craters, free-air activities are markedly  
348 enriched on the southern side, especially at that station most exposed to dominant wind in the SE  
349 sector (Figure 5). It suggests that most radon emissions, either through soil degassing or by plume  
350 outgassing, occurred during the period July-October 2018 when the volcano was more active.  
351 Increased radon activities in soils were previously noted during eruptive periods at Mt. Etna, notably  
352 on the southern flank of the summit area (Neri et al., 2016). However, this is the first time that an  
353 increase in radon activity is observed in a gaseous plume released from the craters of an open-conduit  
354 volcano. A simple wind effect due to a change in wind direction can be ruled out since the wind regime  
355 remained stable between the two periods (Fig. 5e and 5f). In the meantime, as the summit craters  
356 were progressively reactivating, SO<sub>2</sub> flux analysis suggests a gradual increase of the degassing activity  
357 between May and October 2018 (see Supplementary Material). Even though the day-to-day variability  
358 of SO<sub>2</sub> flux is high, both mean and maximum SO<sub>2</sub> fluxes are higher during the second period as well as  
359 the detrended cumulated SO<sub>2</sub> flux values (see Supplementary Material). Although the time-evolution  
360 of radon activity in the plume of Etna is based on rather limited number of samples, its apparent

361 correlation with SO<sub>2</sub> fluxes in a period of progressive unrest may give expectancies for the potential of  
362 in-air radon measurements as a tracer of volcanic activity.

363 **[23]** Furthermore, while radon activity in the volcanic plume could be up to 15 times higher during the  
364 July-October period (Table 1; Figure 5), it is worth noting that the SO<sub>2</sub> flux showed a much more limited  
365 increase, by about 10% (see Supplementary Material). It is well known that variations in SO<sub>2</sub> fluxes  
366 released in the atmosphere are directly proportional to the magma influx at depth (Andres et al., 1993).  
367 Hence, despite slightly increased SO<sub>2</sub> degassing during the second period, it can be assumed that the  
368 amount of magma degassing per unit of time did not drastically change between the two periods. In  
369 such a case, theoretical models predict that the flux of radon produced in the degassing magma is  
370 constant (Terray et al., 2018). However, because radon is a radio-isotope with a short half-life (3.8  
371 days), radon activity in the gas phase can vary according to the transfer time of gases from the  
372 degassing reservoir to the surface (Terray et al., 2018). We can assume that the 15 times increase in  
373 radon activity between the two exposure periods was solely due to a transfer time variation, which  
374 would be the case if the mean plume dilution rate at the monitoring station was not significantly  
375 different for the two periods and if the contribution of steaming fumaroles was negligible. An increase  
376 in radon activity by a factor of 15 would be achieved in 3.9 radon half-lives. In other words, the  
377 observed increase in radon activity could be explained by a transfer time of gases 15 days shorter after  
378 the beginning of the July 2018 volcanic unrest. The <sup>210</sup>Pb-<sup>210</sup>Bi-<sup>210</sup>Po systematics in Mt. Etna gases  
379 allowed estimating a gas transfer time in the range of 1-3 days during eruptive events (Terray et al.,  
380 2018) and up to 17 days during quiescent degassing (Lambert et al., 1985). Although the 15-day shorter  
381 transfer time deduced from the present study corresponds to a maximum estimate, it is in fair

382 agreement with the difference between the estimates of Lambert et al. (1985) and those of Terray et  
383 al. (2018). It thus suggests, in agreement with the moderate increase in SO<sub>2</sub> flux, that the summer 2018  
384 eruptive activity was not triggered by an important reinjection of deep volatile-rich magma in the  
385 shallow plumbing system but instead by the shallower degassing of the already present magma batch  
386 (shorter transfer time of gases leading to higher radon activities). We propose that in-air <sup>222</sup>Rn activities  
387 - thanks to the radioactive properties of radon which make it sensitive to degassing kinetics and, hence,  
388 degassing depth - could be an interesting monitoring parameter in addition to SO<sub>2</sub> and other  
389 geochemical and geophysical methods.

#### 390 *5.4 Radiological effects and radon hazard assessment*

391 **[24]** The European regulations for public exposure to radon (EURATOM, 2013) recommend that radon  
392 activity in working places always remains below the threshold of 300 Bq/m<sup>3</sup> because of the potential  
393 damages of this radioactive gas to the respiratory system. Exposure to high levels of radon has been  
394 recognized as a major cause of lung cancer (Lubin et al., 1995). Two hotspots where radon activities  
395 exceed by far this threshold were found on the crater rim of Mt. Etna, on each side of the small hill  
396 between the Voragine and Bocca Nuova craters (Fig. 4b). Radon activities as high as 1 kBq/m<sup>3</sup> are rare  
397 for outdoor environments and indicate that volcanic exhalations are a major source of radioactivity  
398 into the local air. Accordingly, the radon uptake through inhalation may be of concern for those people  
399 who either visit the volcano or work on it (e.g., volcano guides, scientists). Radon activities measured  
400 at one meter of elevation above the ground are the most relevant to assess the respiratory uptake.  
401 For activities between 1.1 and 8.8 kBq/m<sup>3</sup> (Table 1), the radiological dose rate can be calculated in the

402 range 16-131  $\mu\text{Sv/h}$  using a conversion coefficient of  $1,5 \cdot 10^{-5}$  mSv per  $\text{Bq.h.m}^{-3}$  (obtained from a dose  
403 coefficient of 6,7 mSv per  $\text{mJ.h.m}^{-3}$  and an equilibrium factor of 0.4 between radon and its daughters)  
404 as recommended by the International Commission on Radiological Protection (norm 137, Paquet et  
405 al., 2017). For tourists spending a few tens of minutes at the summit of Mt. Etna once in a lifetime, the  
406 equivalent dose transmitted to their body remains very low and most likely harmless. For instance, a  
407 tourist walking on the path around the Central Crater, spending 10 minutes close to the Voragine  
408 hotspot and 20 minutes on the southern slope, would receive a dose of ca. 27  $\mu\text{Sv}$ , which is only 2% of  
409 the worldwide typical yearly exposure to radon. However, for volcano guides spending up to 4 hours  
410 per day at the summit of the volcano, this on a daily basis all the touristic season long, the dose rate  
411 may be significantly higher. In a probable scenario of 30 minutes exposure at the identified radon  
412 hotspots once a day, the received radiological dose can be computed as:  $(131 \times 10' / 60' + 16 \times 20' / 60') \times$   
413  $10^{-3}$  (mSv/working day)  $\times 100$  (working day/y) (assuming the season peak lasts from early May to late  
414 September with 5 working days a week) = 2.7 mSv/yr. This value is twice higher than the typical  
415 exposure due to radon (1.26 mSv/yr, UNSCEAR, 2008). Although many other factors - out of the scope  
416 of the present study - should be considered in order to refine this assessment (radon daughters  
417 concentrations, radioactive aerosol particle size distribution, exact duration of exposure, use of  
418 individual protective devices such as gas masks), the present study strongly suggests that radon should  
419 be included in future studies on volcanic-gas-related health hazards.

420

421

## 422        **6) Conclusions**

423        **[25]** This first experiment of radon dosimetry in air at an active volcano revealed free-air radon levels  
424        significantly higher than the atmospheric background in the zones most exposed to volcanic gases (up  
425        to a few kBq/m<sup>3</sup>). Radon in such a dynamic environment could come from diffuse soil degassing, low-  
426        to mid-temperature steaming fumaroles and from the main gas plume made of primary magmatic  
427        vapor. In the lack of a detailed knowledge of local meteorological effects inside the Central Crater of  
428        Mt. Etna, the contribution of each potential source of radon could not be deciphered. However, in the  
429        SE sector of the Central Crater, the most exposed to the volcanic plume because of the main regional  
430        NW wind, a significant radon enrichment was measured in air at 1 m above the ground. This  
431        observation strongly supports high radon concentrations in the main gas plume ( $\approx 550$  Bq/m<sup>3</sup>). This is  
432        the first direct evidence of primary magmatic gases being significantly enriched in radon, which implies  
433        that radon does not completely decay away within magmatic gas bubbles before reaching the surface.  
434        The transfer time of gases between the degassing reservoir and the surface is thus as short as a few  
435        days, or a few weeks at most, thus supporting previous theoretical studies.

436        **[26]** The main degassing pathways, either through open vents or through fracture systems, are  
437        markedly identified by radon hotspots with free-air activities above 1,000 Bq/m<sup>3</sup> and up to 8,800  
438        Bq/m<sup>3</sup>. This observation confirms that radon is a useful geochemical tracer of shallow degassing  
439        processes at active volcanoes. Furthermore, an increase of radon free-air activity in the SE sector, most  
440        exposed to the crater plume, was observed during an episode of eruptive activity, starting in July 2018  
441        and characterized by increasing SO<sub>2</sub> fluxes, volcanic tremor and surface manifestations. Interestingly,

442 radon activities increased up to 15 times during the volcanic unrest. Such pattern is best explained by  
443 a 15-day shorter transfer time of gases from a constant volume of magma, or in other words by  
444 degassing occurring at shallower depth beneath the active craters. The results of the study should  
445 encourage further studies on radon in volcanic plumes in order to fully appraise the potential of radon  
446 monitoring in ambient air at active volcanoes as a useful tool for volcano monitoring, in complement  
447 to other geochemical and geophysical parameters. While passive dosimetry appears of interest as an  
448 easy-to-deploy and cheap technology to characterize the baseline of in-air radon activities, efficient  
449 volcanic monitoring will require more sophisticated technologies with near-real time response (e.g.,  
450 Terray et al., 2020). In particular, it will be of the utmost importance to quantify radon fluxes of primary  
451 magmatic origin and to understand how they may vary in relation with shallow magma dynamics.

452 **[27]** Finally, radon activities higher than 1 kBq/m<sup>3</sup> found at some places of Mt. Etna summit area could  
453 cause health concern for regular workers on the volcano. Further studies should be devoted to a  
454 detailed radiological study of exposure to radon of volcanic origin in order to propose individual actions  
455 leading to a mitigation of potential health effects.

456

457

## 458 **Contributions and Acknowledgments**

459 **[28]** LT, VB and PJG designed the passive dosimetry experiment and set it in the field with the help of  
460 OS and others (Clarisse Mallet, LMGE Clermont-Ferrand, Jean-Luc Devidal, LMV Clermont-Ferrand and  
461 Romain Lauzeral, McGill University Montréal) who are warmly thanked. F. Muré is acknowledged for

462 his technical assistance in the management of FLAME SO<sub>2</sub> flux measurement network. All authors  
463 contributed to the ideas presented in this paper and to its writing. We thank the Associate Editor and  
464 anonymous reviewers for their meaningful suggestions and comments which led to improve the  
465 manuscript.

466 **[29]** The scientific support of INGV - Osservatorio Etneo and the logistical help provided by both Parco  
467 dell'Etnea, Funivia dell'Etnea and Gruppo Guide Alpine Etnea Sud & Nord were essential for the success  
468 of this study. This research is part of the project RAVE@Etnea that has received funding from the  
469 European Union's Horizon 2020 research and innovation program under grant agreement N° 654182.  
470 This is Laboratory of Excellence ClerVolc contribution number XXX [NB: ClerVolc number will be  
471 communicated once the manuscript is accepted for publication].

472 **[30]** In order to comply with FAIR standards, the two datasets presented in the manuscript (radon  
473 measurements presented in Table 1 and daily SO<sub>2</sub> flux data provided in Figure 6) are archived in zenodo  
474 general repository (<https://zenodo.org/>) with the DOI 10.5281/zenodo.3560896. These datasets can  
475 be found at <https://zenodo.org/record/3560896>.

683 **Figures and tables**

684

685 **Figure 1:** (a) Map of the summit craters of Mt. Etna (modified from Neri et al., 2017) with the location of the radon  
 686 dosimetry stations (yellow dots represent the stations that were replaced in July and purple dots the other stations). Dotted  
 687 red circles represent the degassing vents active during the period of exposure of dosimeters. VOR stands for the Voragine  
 688 vent and BN1-BN2 for the two Bocca Nuova vents. The radon hotspot in front of VOR vent (see text for details) is indicated  
 689 with an orange frame. Red lines depict the main North-South fractures formed on the rim after the May 2016 eruption  
 690 (drawn after Marchese et al., 2018) (b) Wider view of Mt. Etna summit area (extracted from Google Earth) with the position  
 691 of the four remote reference dosimetry stations. The white frame corresponds to the map in (a).

699

700 **Figure 2:** Mt. Etna summit craters seen from Sentinel 2B satellite during summer 2018. Images on the top correspond with  
 701 the first exposure period (24/05/18-06/07/18, the last image has been captured one day after on 07/07/2018) and images  
 702 on the bottom correspond to the second period (06/07/18-11/10/18). Images have been produced using a combination of  
 703 bands from the L2A level (orthorectified bottom-of-atmosphere reflectance) as follows: Red (Band 12 – Short Wave Infra Red  
 704 – 2190 nm) – Green (Band 11 – Short Wave Infra Red – 1610 nm) – Blue (Band 9 – Water vapour – 945 nm). The spatial  
 705 resolution is 20m for bands 12 and 11 but 60m for band 9. Sentinel products are made publicly available by the European  
 706 Spatial Agency on its website (<https://apps.sentinel-hub.com/eo-browser/>). Red and yellow pixels highlight positive infrared  
 707 thermal anomalies that correspond to the precise location of degassing vents BN1 (Bocca Nuova 1), BN2 (Bocca Nuova 2)  
 708 and VOR (Voragine), possibly related to the presence of very shallow magma. The gas plume escaping from the crater, as  
 709 well as the main fumarole fields, are also visible in blue due to their high water content.

752

753 **Figure 4:** Spatial distribution of ground level (5 cm, left panel) and in free air (1 m, right panel) integrated radon activities  
754 measured in the four different sectors of Mt. Etna Central Crater. Reference stations are represented separately below each  
755 panel. All crater stations are positioned according to the geographical coordinates given in Table 1. Coordinates are  
756 displayed using an UTM (Universal Transverse Mercator) projection relatively to the center of the Central Crater (barycenter  
757 of all station locations). Black star symbols correspond to stations where radon activities could be determined, black cross  
758 symbols correspond to stations where no radon activity is available (see text for explanations) and the red star symbol  
759 correspond to the Voragine hotspot station (see text). Radon activity values are indicated next to each station pictogram  
760 and for the few stations replaced in July 2018 the time-weighted mean value over the two exposure periods is given. A  
761 colored band is also drawn to reflect the spatial distribution of activity values. The color sequence all around the crater is  
762 obtained from a linear interpolation of measured activity in angular coordinates. Voragine station outlier values are  
763 excluded from the color band and the colorscale is logarithmic. The wind rose obtained from Trapani radiosounding (see text  
764 for details) is also represented with a polar histogram. Circles correspond to iso-lines of percentage of occurrence for wind  
765 directions. The bin color refer to the wind speed (see legend on the right side).

767

768 **Figure 5:** Comparison of  $^{222}\text{Rn}$  activity (Fig. 5a to 5d) and wind (Fig. 5e and 5f) between May-July 2018 and July-October  
 769 2018 periods. (a) to (d) - Comparison of  $^{222}\text{Rn}$  integrated activity between the two periods for each of the four stations that  
 770 were replaced in July 2018 (one for each sector of the crater rim). Ground level activities correspond to orange square  
 771 symbols, whereas free-air activities are depicted in blue dot points. Ground-level and free-air reference activities measured  
 772 at remote locations (mean values are given in Table 1) are also indicated in the plot background with orange and blue  
 773 colors, respectively. The same wooden stick was used for the two measurement periods at all stations, except on the NE  
 774 sector where the new station was positioned a few meters away from the former emplacement because of a potential risk of  
 775 destruction due to combustion of the wood. (e) and (f) - Comparison of wind direction and speed between May-July 2018  
 776 and July-October 2018. For both periods the mean speed was 10 m/s with a standard deviation of 7 m/s.

802 **Table 1** (next page): Radon dosimeter results with uncertainty for each dosimeter given at confidence  
803 interval of  $2\text{-}\sigma$ . For the mean values, uncertainty corresponds to the standard error (standard  
804 deviation of the population divided by the square root of the number of elements in the population).  
805 Exposure periods started and ended as follows: May-Oct (24/05/18-11/10/18), May-Jul (24/05/18-  
806 06/07/18) and Jul-Oct (06/07/18-11/10/18). “lost” indicates a dosimeter that was lost during the  
807 experiment, “udl” refers to a dosimeter that yielded results under the detection limit, and “damaged”  
808 corresponds to a dosimeter that was corroded by acids and could not be analyzed or that was clogged  
809 in soldered dust preventing radon from entering the capsule. Note that one station (namely, that  
810 closest to the Voragine vent) was excluded from the computation of the mean value of the NE sector  
811 (see text for explanation).

Station	Lat	Lon	Exposition period	Integrated radon activity (Bq/m <sup>3</sup> )			
				Ground level (5cm)	2σ	Free air (1m)	2σ
