51 Abstract

In France, the frequency of premature rupture of the membranes (PROM) is 2% to 3% before 52 53 37 weeks' gestation (level of evidence [LE] 2) and less than 1% before 34 weeks (LE2). 54 Preterm delivery and intrauterine infection are the major complications of preterm PROM 55 (PPROM) (LE2). Prolongation of the latency period is beneficial (LE2). Compared with other 56 causes of preterm delivery, PPROM is associated with a clear excess risk of neonatal 57 morbidity and mortality only in cases of intrauterine infection, which is linked to higher rates 58 of in utero fetal death (LE3), early neonatal infection (LE2), and necrotizing enterocolitis 59 (LE2).

The diagnosis of PPROM is principally clinical (professional consensus). Tests to detect
IGFBP-1 or PAMG-1 are recommended in cases of uncertainty (professional consensus).

62 Hospitalization is recommended for women diagnosed with PPROM (professional 63 consensus). Adequate evidence does not exist to support recommendations for or against 64 initial tocolysis (Grade C). If tocolysis is prescribed, it should not continue longer than 48 hours (Grade C). The administration of antenatal corticosteroids is recommended for fetuses 65 with a gestational age less than 34 weeks (Grade A) and magnesium sulfate if delivery is 66 imminent before 32 weeks (Grade A). The prescription of antibiotic prophylaxis at admission 67 is recommended (Grade A) to reduce neonatal and maternal morbidity (LE1). Amoxicillin, 68 69 third-generation cephalosporins, and erythromycin (professional consensus) can each be used individually or eythromycin and amoxicillin can be combined (professional consensus) 70 71 for a period of 7 days (Grade C). Nonetheless, it is acceptable to stop antibiotic prophylaxis 72 when the initial vaginal sample is negative (professional consensus). The following are not 73 recommended for antibiotic prophylaxis: amoxicillin-clavulanic acid (professional consensus), 74 aminoglycosides, glycopeptides, first- or second-generation cephalosporins, clindamycin, or 75 metronidazole (professional consensus).

Women who are clinically stable after at least 48 hours of hospital monitoring can bemanaged at home (professional consensus).

Monitoring should include checking for clinical and laboratory factors suggestive of intrauterine infection (professional consensus). No guidelines can be issued about the frequency of this monitoring (professional consensus). Adequate evidence does not exist to support a recommendation for or against the routine initiation of antibiotic therapy when the monitoring of an asymptomatic woman produces a single isolated positive result (e.g., elevated CRP, or hyperleukocytosis, or a positive vaginal sample) (professional consensus).

In cases of intrauterine infection, the immediate intravenous administration (Grade B) of antibiotic therapy combining a beta-lactam with an aminoglycoside (Grade B) and early delivery of the child are both recommended (Grade A). Cesarean delivery of women with intrauterine infections is reserved for the standard obstetric indications (professional consensus).

Expectant management is recommended for uncomplicated PROM before 37 weeks (Grade
A), even when a sample is positive for Streptococcus B, as long as antibiotic prophylaxis
begins at admission (professional consensus). Oxytocin and prostaglandins are two possible
options for the induction of labor in women with PPROM (professional consensus).

109 **1. Introduction**

110 The sponsor (the French College of Gynecologists and Obstetricians (CNGOF)) appointed a 111 steering committee (Appendix A) to define the exact questions to be put to the experts, to 112 choose them, follow their work and draft the synthesis of recommendations resulting from 113 their work [1]. The experts analyzed the scientific literature on the subject to answer the 114 guestions raised. A literature review identified the relevant articles through mid-2018 by 115 searching the MEDLINE database and the Cochrane Library. The search was restricted to 116 articles published in English and French. Priority was given to articles reporting results of 117 original research, although review articles and commentaries were also consulted. 118 Guidelines published by organizations or institutions such as the American College of 119 Obstetricians and Gynecologists (ACOG), the Royal College of Obstetricians and 120 Gynaecologists (RCOG), the Canadian Society of Gynecology and Obstetrics (SOGC), the 121 National Institute for Health and Clinical Excellence (NICE) as well as previous guidelines 122 published by the CNGOF were reviewed, and additional studies were located by reviewing 123 bibliographies of identified articles. For each question, each overview of validated scientific 124 data was assigned a level of evidence based on the quality of its data, in accordance with the framework defined by the HAS (French Health Authority), summarized below. Details on the 125 126 systematic review process are provided in each article [2-8] dealing with the questions raised 127 in the Content section.

128

129 1.1. Quality of evidence assessment

LE1: very powerful randomized comparative trials, meta-analysis of randomized comparativetrials;

LE2: not very powerful randomized trial, well-run non-randomized comparative studies,cohort studies;

134 LE3: case-control studies;

LE4: non-randomized comparative studies with large biases, retrospective studies, cross-sectional studies, and case series.

A synthesis of recommendations was drafted by the organizing committee based on the
replies given by the expert authors. Each recommendation for practice was allocated a
grade, defined by the HAS as follows:

140

141 1.2. Classification of recommendations

142 Grade A: Recommendations are based on good and consistent scientific evidence

143 Grade B: Recommendations are based on limited or inconsistent scientific evidence

144 Grade C: Recommendations are based primarily on consensus and expert opinion

145 Professional consensus: In the absence of any conclusive scientific evidence, some 146 practices have nevertheless been recommended on the basis of agreement between the

147 members of the working group (professional consensus).

148

All texts were reviewed by persons not involved in the work, i.e., practitioners in the various specialties (Appendix) concerned and working in different situations (public, private, university or non-university establishments). Once the review was completed, changes were made, if appropriate, considering the assessment of the quality of the evidence.

153 The original long texts in French are cited [2-8], but their individual references are not 154 included here in view of the enormous space they would occupy in this article intended to 155 summarize the guidelines.

156

157 **2.** Epidemiology, risk factors, and the child's prognosis (2)

According to the 2016 French national perinatal survey, premature rupture of the membranes (PROM) before 37 weeks occurs in 2-3% of pregnancies, and PROM before 34 weeks in less than 1% (LE2). Its frequency increases as the pregnancy advances (LE2) and is higher in multiple than in singleton pregnancies (LE2). Most women give birth in the week that follows the rupture, and the duration of latency (defined as the interval between PROM and the birth) diminishes as gestational age at PROM rises (LE2). Many factors are associated with the prolongation (low gestational age) or shortening (multiple pregnancy, cervical 165 modifications, oligohydramnios, infection, placental detachment, or cord prolapse) of the166 latency period after preterm PROM.

The major risk factors for PPROM are a history either of it or of preterm delivery (LE3), cervical abnormalities before pregnancy (LE4), vaginal bleeding (LE4), cervical shortening during pregnancy (LE2), genital infections by chlamydiae and/or gonorrhea (LE3), and intrauterine infection (LE3). Most patients, however, present no risk factors (LE2). The risk of recurrence during subsequent pregnancies ranges from 6% to 17%, regardless of gestational age at the index PROM (LE3). No model for individual prediction of the risk of PPROM has been validated, and their use in clinical practice is not recommended (Grade B).

Preterm delivery and intrauterine infection (a term preferable to the overly imprecise chorioamnionitis [professional consensus]) are the major complications of PPROM (LE2). Other obstetric complications (such as cord prolapse or placental detachment) are rarer, but they too affect prognosis and therefore management (LE3). The risk of complications diminishes as gestational age at PROM rises (LE2). Regardless of the cause of delivery, gestational age at birth is the principal determinant of the preterm child's survival (LE2). Prolongation of the latency period is beneficial for the child (LE2).

181 At the same gestational age, the studies with the highest level of evidence do not show any 182 excess risk of mortality for preterm births associated with PPROM, compared with those 183 involving spontaneous labor with intact membranes (LE2). The risks of intraventricular 184 hemorrhage, late neonatal bacterial infection, retinopathy of prematurity, or long-term 185 cognitive disorders do not seem higher in cases of PPROM compared with other causes of 186 preterm delivery (LE2). Higher risks of periventricular leukomalacia (LE2), early neonatal 187 bacterial infection (LE2), bronchopulmonary dysplasia (LE2), or cerebral palsy (LE2) are 188 found, although inconsistently, often in subgroups, perhaps explained by the differences in 189 the choice of comparison group and of adjustment strategy.

190 Intrauterine infection is associated with an increased risk of in utero fetal death (LE3), early 191 neonatal bacterial infection (LE2), and necrotizing enterocolitis (NEC) (LE2). Its association 192 with the newborn's neurological morbidity remains controversial. Intrauterine infection is not associated with a higher risk of neonatal mortality (LE4), sensory impairment (retinopathy of
prematurity, blindness, deafness) (LE2), or bronchopulmonary dysplasia (LE2).

195

196 **3. Diagnosis (3)**

197 PROM is noticed most often by the discharge of amniotic fluid, easily recognizable. In these198 cases a laboratory diagnostic test is not required (professional consensus).

199 Ultrasound assessment of the quantity of amniotic fluid cannot either confirm or rule out the 200 diagnosis of PROM (LE4). In uncertain clinical situations, an immunochromatographic test to 201 detect Insulin-like Growth Factor-Binding Protein-1 (IGFBP-1) or Placenta Alpha 1-202 Microglobulin (PAMG-1) is recommended to diagnose PROM, although it has not been 203 demonstrated that their use reduces either neonatal or maternal morbidity (professional 204 consensus). These tests have better sensitivity and specificity than the other biochemical 205 markers (LE3). If one of these tests is negative, PROM is very improbable (LE3). Moreover, 206 a positive result on the IGFBP-1 or PAMG-1 must not be considered dispositive proof of 207 PROM because of the risk of a false positive finding, especially when cervical modifications 208 are also present (professional consensus).

209

210

4. Therapeutic management (excluding antibiotic therapy) (4)

The woman should be hospitalized at diagnosis of preterm PROM if the fetus has reached viability (professional consensus). Clinical examination aims to look for signs of intrauterine infection: fever, fetal tachycardia, uterine contractions, or purulent vaginal discharge (professional consensus). If a cervical evaluation seems necessary, an examination by speculum or a digital or ultrasound cervical examination can be performed (professional consensus). Cervical assessments should be limited, regardless of the method used (professional consensus).

218 Samples for a complete blood count, CRP assay, and urinary and vaginal bacteriological 219 testing should be taken at admission, before the administration of any antibiotics 220 (professional consensus). In cases of a positive vaginal culture, an antimicrobial susceptibility test is recommended to guide the antibiotic therapy in case of intrauterineinfection and early neonatal bacterial infection (professional consensus).

223 Ultrasound should be performed to determine the fetal position, locate the placenta, and 224 estimate fetal weight and the quantity of residual amniotic fluid (professional consensus).

225 Antenatal corticosteroids should be administered if the fetus's gestational age is less than 34 226 weeks (Grade A) and magnesium sulfate if delivery is imminent before 32 weeks (Grade A). 227 In the absence of any demonstrated neonatal benefits, there is not sufficient evidence to 228 recommend (or to recommend against) initial tocolysis for preterm PROM (Grade C). If tocolysis is prescribed, it should not continue longer than 48 hours (Grade C). There is no 229 230 evidence to justify a recommendation either for or against vitamin supplementation (vitamin 231 C and E) (professional consensus). Strict bed rest should not be recommended (professional 232 consensus). For women with a cerclage at admission, there is not adequate evidence to 233 recommend its removal or maintenance at admission (professional consensus). However, if 234 clinical or laboratory signs suggest intrauterine infection, the cerclage should be immediately 235 removed (professional consensus).

Women who are clinically stable after at least 48 hours of hospital monitoring can be managed at home (professional consensus). On the other hand, it is not possible to offer criteria for selecting women eligible for home management (professional consensus).

239 Monitoring should include checking for clinical and laboratory factors suggestive of 240 intrauterine infection (professional consensus). No adequate evidence justifies guidelines 241 about the frequency of this monitoring (professional consensus).

Finally, couples must be adequately informed of the situation and the information they receive should be adapted to the clinical course as it progresses. This information must be provided by an obstetrician and a pediatrician (professional consensus).

245

5. Choices and duration of antibiotic prophylaxis (5)

Antibiotic prophylaxis should be prescribed at admission for preterm PROM (Grade A), because it is associated with a reduction in neonatal morbidity and maternal (LE1). 249 *Streptococcus agalactiae* (group-B streptococci) and *Escherichia coli* are the principal 250 infectious agents involved in early neonatal bacterial infection (LE3) and should be the target 251 of the antibiotic prophylaxis (professional consensus).

252 Theoretical arguments indicate that amoxicillin (parenteral or oral) or third-generation 253 cephalosporins (parenteral) can each be used alone, but they have not been evaluated for 254 this indication (professional consensus). In older studies of uncertain external validity, given 255 the evolution in bacterial ecology, erythromycin, both with and without amoxicillin (parenteral 256 or oral), showed neonatal benefits (LE1). These substances can therefore be used (professional consensus). The following are not recommended as antibiotic prophylaxis: 257 258 amoxicillin-clavulanic acid (professional consensus), aminoglycosides, glycopeptides, first- or 259 second-generation cephalosporins, clindamycin, or metronidazole (professional consensus).

Antibiotic prophylaxis should be prescribed for a period of 7 days (Grade C). Nonetheless, as bacterial resistance develops after long treatments, stopping this antibiotic prophylaxis early appears acceptable, even though it has not been assessed in this situation of an initial vaginal sample that turned out to be negative (professional consensus). If the vaginal sample is positive at admission, adaptation of the antibiotic prophylaxis to the culture and to the antibiotic susceptibility testing must be discussed (professional consensus).

Routine repetition of antibiotic prophylaxis is not recommended during the latency period or when elevated CRP is the only sign, or when vaginal bacteria carriage is asymptomatic (professional consensus).

The literature includes no data about antibiotic prophylaxis during labor after preterm PROM in asymptomatic women. In this context, the French Society of Neonatology (SFN) has issued guidelines applicable to fetuses from 34 weeks of gestation.

272

273

6. Intrauterine infection: diagnosis and treatment (6)

274 Intrauterine infection can be clinically diagnosed when all of the following criteria are met275 (professional consensus):

Fever, defined by a maternal temperature equal to or greater than 38°C, confirmed after an interval of 30 minutes, with no nongynecologic infectious cause identified, associated with at least two of the following criteria:

- persistent fetal tachycardia > 160 bpm,

- uterine pain or painful uterine contractions or spontaneous labor,

281 - purulent amniotic fluid.

Maternal plasma CRP and hyperleukocytosis have limited value for the diagnosis of intrauterine infection (LE3). In asymptomatic women, a plasma CRP level less than 5 mg/l makes it possible to rule out the diagnosis (LE3). The plasma CRP assay is thus recommended for its negative predictive value (Grade C). The interpretation of maternal hyperleukocytosis results must not be interpreted too close in time to any corticosteroid therapy (professional consensus).

288 Bacteriological examination of the amniotic fluid, collected by amniocentesis, is not 289 recommended for the diagnosis of intrauterine infection (professional consensus).

290 In cases of intrauterine infection, intravenous antibiotic therapy must be administered 291 immediately to reduce the risks of maternal and neonatal infectious complications (Grade B). 292 It must be effective against S. agalactiae and E. coli (professional consensus). The spectrum 293 can be expanded in cases of serious infection or when infection to resistant bacteria is 294 suspected or documented (professional consensus). The antibiotic therapy must include a 295 combination of a beta-lactam and an aminoglycoside (Grade B). The most appropriate 296 aminoglycoside is gentamicin, by a daily intravenous injection (professional consensus). 297 Depending on the local bacteriological ecology, the results of prenatal samples, and maternal 298 sepsis, the beta-lactam can be chosen from among amoxicillin, a third-generation 299 cephalosporin, or, in cases of a serious allergy to beta-lactams, aztreonam (professional 300 consensus). Aztreonam requires the addition of a substance that acts against gram-positive 301 bacteria (professional consensus). For women with cesareans, the data are insufficient to 302 recommend using (or not using) clindamycin or metronidazole to reduce the risk of 303 postoperative infection by anaerobic bacteria (professional consensus).

The treatment must begin as soon as the infection is diagnosed and continue during labor (Grade B). In the postpartum period, a single supplementary dose is generally sufficient after vaginal delivery (professional consensus). Antibiotic use must be extended in the presence of a blood infection (professional consensus). The persistence of fever at 48 hours, obesity, or a cesarean delivery can also suggest prolongation of the treatment (professional consensus).

In cases of intrauterine infection identified after PROM, delivery of the child is recommended (Grade A). There is no proof that cesarean delivery is associated with an improvement of the neonatal prognosis, regardless of gestational age. Intrauterine infection alone does not justify cesarean delivery (professional consensus), which remains reserved for the standard obstetric indications (professional consensus).

315

316

6 7. Mode of delivery in the absence of complications (7)

317 Because a long latency period is not associated with an increased risk of neonatal 318 complications before 34 weeks (LE3), it is recommended that labor not be induced for 319 uncomplicated PROM (Grade C).

320 After 34 weeks of gestation, regardless of the gestational age at which PROM occurred, 321 expectant management is associated with a higher frequency of intrauterine infection (LE2) 322 but not of neonatal sepsis (LE1). An interventionist attitude is associated with higher rates of 323 respiratory distress (LE2) and cesarean delivery (LE2), and with longer hospitalization in 324 neonatal special care units (LE2). Expectant management is recommended for 325 uncomplicated PROM before 37 weeks (Grade A), even when a sample is positive for 326 Streptococcus B, as long as antibiotic prophylaxis begins at admission (professional 327 consensus).

328 Oxytocin and prostaglandins are two possible options for the induction of labor in women 329 with preterm PROM (professional consensus). The current data are too limited to enable a 330 recommendation about the use of a transcervical balloon for this indication (professional 331 consensus).

332 8. PROM before fetal viability (8)

Previable PROM, that is, PROM before fetal viability, is rare, with a frequency ranging from 0.3% to 1% (LE4). After previable PROM, 50% to 60% of women nonetheless retain a satisfactory quantity of amniotic fluid (LE3), 23% to 53% give birth in the week after PROM, and slightly more than 35% of the women have not given birth 2 weeks after PROM (LE3). Oligohydramnios during the initial ultrasound is associated with a higher risk of a short latency period (LE4).

339 The frequency of medical terminations of pregnancy varies strongly between studies and 340 depends especially on the laws of the country in which they occur (LE4). Hospital survival 341 rates reported after various conservative treatments range from 17% to 55%, depending on 342 the series (LE4), and survival without major morbidity ranges from 26% to 63% (LE4). 343 Survival increases with gestational age at PROM and decreases when oligohydramnios is 344 present (LE4). The perinatal prognosis of PROM depends largely on the extent of 345 prematurity, especially for extremely preterm birth and its complications (LE3). Although at 346 the same gestational age, neonatal mortality does not appear to be higher for previable 347 PROM than for spontaneous preterm delivery (LE3), it nonetheless seems that neonatal and 348 longer-term morbidity for the children born after 24 weeks of gestation is higher for preterm 349 deliveries after previable PROM than for spontaneous preterm births that involved neither 350 PROM nor induction of preterm birth (LE3).

The estimated frequency of pulmonary hypoplasia related to PROM ranges from 1.7% to 29% (LE4). The risk of pulmonary hypoplasia is associated with the earliness of PROM, the residual amniotic fluid volume, and the length of the latency period (LE4). No tool for the antenatal diagnosis of pulmonary hypoplasia currently exists (LE4).

The frequency of clinical intrauterine infection varies substantially between studies. For PROM before 24 weeks treated conservatively, it ranges from 16% to 71% (LE4). The frequency of maternal sepsis varies from 0.8% to 4.8% in the most recent studies, in which antibiotics were used routinely (LE4). Although the literature contains only one case report of 359 maternal death after previable PROM, French confidential enquiries into maternal deaths
360 identified 3 cases between 2007 and 2012 (LE3).

Information is a component in its own right of the care to be provided to women with previable PROM and their partners. Parents must receive this information from physicians well aware of the risks associated with previable PROM and with the options for its management. Its contents must be appropriate to the situation and the potential developments and must cover both the prenatal and postnatal periods (professional consensus).

An initial period of hospitalization can be proposed to women with spontaneous previable PROM (professional consensus). Before fetal viability, this initial hospitalization need not occur in a level-3 referral perinatal center (professional consensus). Prophylactic antibiotic treatment is recommended, as described in section 4 (professional consensus).

The gestational age at which this treatment begins depends on the thresholds chosen for active care in the NICUs within maternity units and perinatal networks. It should consider most especially the parents' position (professional consensus). In view of the absence of any evidence that tocolysis is beneficial and the infectious risk associated with previable PROM, no recommendation is made about tocolysis in previable PROM (professional consensus).

In view of the prognostic importance of the quantity of amniotic fluid, its ultrasound evaluation
can be proposed at the initial consultation and after a delay of 7 to 14 days if the delivery has
not taken place (professional consensus).

379 Termination of pregnancy can take place at "any point during the pregnancy" in accordance 380 with the strict conditions set forth by the Public Health Code article L2213-1, "either the 381 continuation of the pregnancy seriously threatens the woman's health, or there is a strong 382 probability that the child to be born is affected by a very severe condition recognized as 383 incurable at the time of diagnosis." Accordingly, the provision of information must begin from 384 the diagnosis of PROM and concern intrauterine infections that suggest the development of 385 severe maternal sepsis so that the doctor can, should overt infection develop and in the 386 absence of spontaneous labor, begin a discussion of elective abortion that can be performed in a delay appropriate to the clinical situation and laboratory results (professional
consensus). In this situation, the opinion of the multidisciplinary center of prenatal diagnosis
(CPDPN) is not necessary, but the attestation must be signed by 4 persons including at least
one expert physician on an official CPDPN list.

In the absence of elements likely to threaten the mother's health, the child's prognosis can lead the CPDPN to accept the mother's request to terminate the pregnancy. All situations, however, are not equivalent in terms of prognosis. Some factors have a major prognostic weight. These include gestational age at PROM, its spontaneous or induced nature, and oligohydramnios at 7 and/or 14 days after PROM. It is thus therefore important to focus on assessing these prognostic factors and not to rush a possible request in the absence of an emergency motivated by a threat to the mother's health.

After the initial hospitalization, there is no evidence on which to base a recommendation for further hospital management rather than return home, as long as there is no clinical or laboratory evidence of intrauterine infection (professional consensus).

401 Cases of previable PROM that follow amniocentesis have a better prognosis than 402 spontaneous previable PROM (LE3). In the absence of research to define management in 403 these cases of iatrogenic PROM, no guidelines can be issued for them.
