ABSTRACT

In this study, we focus on a partially melted garnet-bearing granulite from the Salvador-Esplanade belt (Salvador da Bahia, Brazil), and examine the behavior of major and trace elements during partial melting and melt-driven metasomatism. Phase equilibria modeling and U-Th-Pb geochronology shows that the sample underwent partial melting during the heating segment of the decompression path from ~ 1.2 GPa and 675-700°C to ~ 0.8 GPa and 790°C at ca. 2.06 Ga. During the last stage of decompression, from 0.8 to ~ 0.5 GPa, physical segregation of melt resulted in the establishment of chemical potential gradients and mass transfer between the host-granulite and the leucosome. Modelling shows that H_2O, CaO, K_2O and Na_2O diffuse from the melt into the host residue, whereas SiO_2 is transferred from the host-granulite into the adjacent leucosome. Opposed senses of diffusional transfer resulted in the formation of a quartz-rich anhydrous leucosome and a quartz-undersaturated selvage in the host-granulite. Compositional maps show that garnets exhibit unusual and contrasting major and trace element distribution depending on their textural position. The largest garnets located in the quartz-undersaturated selvage preserve their original Ca and trace element growth zoning. A transition from bell-shaped profiles for Y and HREEs to bowl-shape profiles for LREEs is consistent with a typical Rayleigh fractionation model, fast intergranular element mobility and rock-wide equilibrium during prograde partial melting. In contrast, smaller garnets away from the leucosome show evidence of prograde growth zoning modified by intragranular diffusion, as evidenced by a network of open channels and healed-cracks that act as connecting pathways between the matrix and garnet core. This results in either subtle modification of both major and trace elements adjacent to the inner core inclusions, or a complete re-equilibration. The recognition that the initial Ca growth zoning, including the inner core compositions, was later modified by intragranular diffusion implies that misleading thermobarometric results and tectonic interpretations would be obtained if the garnet core composition was used to fingerprint the early garnet nucleation stage. This study further demonstrates that at high

55 temperature (> 750°C) and in the presence of melt, REE are not less vulnerable to diffusive
56 resetting than divalent cations like Ca^{2+}.

1. INTRODUCTION

Partial melting is a fundamental process for differentiating (Brown, 2010) and weakening the deep crust (Piazolo, Daczko, Silva & Raimondo, 2020; Rosenberg & Handy, 2005), which in turn exerts a first-order control on deformation style, lateral redistribution of mass, crustal thickness and surface topography (Beaumont, Jamieson, Nguyen & Medvedev, 2004; Hollister & Crawford, 1986; Jamieson, Unsworth, Harris, Rosenberg & Schulmann, 2011; Rabin, Trap, Carry, Fréville & Cenki-Tok, 2015; Royden et al., 1997; Vanderhaeghe, 2012). Exhumed migmatites preserve, through their mineralogy and structure, a wealth of information that can be used to decipher the thermo-mechanical behavior of orogenic continental crust. With this motivation, the petrological analysis of partially melted feldsic rocks is now commonplace in metamorphic petrology, thanks to extended experimental work (e.g. Clemens, 1984; Grant, 1985; Le Breton, 1988; Thompson, 1982; Vielzeuf & Holloway, 1988; Vielzeuf & Montel, 1994) and thermodynamic phase relation modeling (Holland & Powell, 2001a; Spear, Kohn & Cheney, 1999; Vielzeuf & Schmidt, 2001; White, Powell & Holland, 2001; White & Powell, 2010). Despite this progress, modeling phase relations in migmatites is not trivial because they are subject to redistribution and transfer of the highly mobile melt component at various scales, from grain- to crustal-scale (Etheridge, Daczko, Chapman & Stuart, 2020; Sawyer, 2001). Therefore, phase relation modeling in migmatites requires the consideration of not only changes in environmental variables like pressure and temperature, but also the variation of the equilibrium volume and composition of the system (i.e. open system processes).

Modeling the role of melt transfer (loss and gain) on phase relations has been extensively investigated (Alessio, Hand, Morrissey, Kelsey & Payne, 2017; Bartoli, 2017; Dumond, Goncalves, Williams & Jercinovic, 2015; White et al., 2001; Yakymchuk & Brown, 2014;). Among the many benefits of open system forward modeling is the application of a melt-reintegration approach that consist of recovering the bulk composition prior to any melt transfer. This method allows investigating the prograde evolution of melt-bearing systems that tend to be obliterated by continuous re-equilibration up to peak metamorphic conditions. Another complexity arising from

the segregation of melt from the solid residue is that the system becomes physically and chemically differentiated into melt-rich domains (leucosome) and solid-rich domains (melanosome). The thermodynamic system is therefore composed of two sub-systems that will interact, with changing pressure and temperature conditions, due to the establishment of chemical potential gradients of components at the interface between both sub-systems (White & Powell, 2010). The diffusion of components (H_2O, SiO_2,...) between the two sub-systems produces significant variations in composition, mineral reactions and assemblages (Fitzsimons, 1996; White & Powell, 2010). Despite this conceptual framework being generally accepted, melt-rock interaction in segregated migmatites remains rarely identified via textural, geochemical and/or mineralogical evidence, nor investigated via thermodynamic modeling (Kriegsman & Hensen, 1998; Lin & Sawyer, 2019; White & Powell, 2010).

In migmatites, garnet is very common as a peritectic phase and has the ability to preserve zoning of divalent cations (Fe, Mg, Ca and Mn) that reflects changing P-T conditions and/or bulk rock chemistry, either due to garnet fractionation or mass transfer during melt segregation, transport and interaction with the garnet-bearing residual rock (e.g. Caddick, Konopásek & Thompson, 2010; Konrad-Schmolke, O'Brien, de Capitani & Carswell, 2008). To retrieve the maximum information related to garnet chemical evolution, the characterization of major element zoning can be complemented with trace elements (Hyppolito et al., 2019; Raimondo et al., 2017). Trivalent cations, like rare-earth elements, have lower diffusion coefficients than major divalent cations. They are therefore more resistant to diffusional modification and allow the preservation of prograde and high temperature processes (Carlson, 2012; Gaidies et al., 2020; George & Gaidies, 2017; Moore, Carlson & Hesse, 2013; Rubatto et al., 2020), including those involved during partial meting (Dumond et al., 2015).

The trace element characteristics of garnet can be linked to the evolution of accessory phases used for geochronology (e.g. monazite, zircon and rutile) to better constrain tectonometamorphic histories (Dumond et al., 2015; Hermann & Rubatto, 2003; Mahan, Goncalves, Williams & Jercinovic, 2006; Prent et al., 2019; Pyle & Spear, 2003; Tomkins & Pattison, 2007; Weller, jackson, Miller, St-Onge & Rayner, 2020). They also provide insight into

the mechanisms controlling the uptake (interface- vs diffusion-controlled growth) and mobility of trace element during metamorphism and metasomatism (George, Gaidies & Boucher, 2018; Konrad-Schmolke, Zack, O'Brien & Jacob, 2008; Moore et al., 2013; Raimondo et al., 2017; Skora et al., 2006). With the recent development of in-situ laser ablation - inductively coupled plasma - mass spectrometry (LA-ICP-MS), it is now possible to rapidly and quantitatively map the 2D distribution of trace elements across major and accessory minerals of interest (George et al., 2018; Raimondo et al., 2017; Ubide, McKenna, Chew & Kamber, 2015). Yet, despite the known benefits of analyzing trace elements in garnet for the purposes listed above, there remains a limited number of studies using this approach to understand the grain-scale controls on garnet crystallization (Gaidies et al. 2020; George et al., 2018; Rubatto et al. 2020).

In this contribution, we report the integrated petrological and geochemical characterization of a high-grade rock that preserves evidence of changes in P-T conditions, partial melting and melt-driven metasomatism. The selected sample, from the São Francisco craton in Brazil, is a layered composite rock that consists of a garnet-bearing quartz-saturated host granulite, a quartzo-feldspatic leucosome, that may correspond to crystallized segregated melt or differentiated melt residue (Guernina & Sawyer, 2003), and a quartz-undersaturated garnet-bearing selvage formed at the interface between the host-granulite and leucosome. Petrological analysis and thermodynamic modeling (using P-T-μ-X phase diagrams, where μ = chemical potential and X = composition) shows that the distinct mineralogy of the selvage is the result of mass transfer driven by chemical potential gradients established between the host-granulite and the segregated melt during decompression. In addition, garnets show a consistent change in grain size, morphology, major and trace element composition and zoning patterns across the gneissic layering, as revealed by quantified LA-ICP-MS raster maps. The strong correlation between textural position and zoning pattern in garnet gives insight into the grain-scale petrogenetic processes involved in partially-molten granulites. We distinguish the role of (1) intergranular mobility of elements and accessory phases during metamorphic garnet growth; and (2) post-growth intragranular diffusion of major and trace elements during melt-driven metasomatism.

2. GEOLOGICAL SETTING

2.1. São Francisco craton and the Salvador-Esplanade belt

The São Francisco Craton, located in the east-central part of Brazil, consists of an Archean to Paleoproterozoic crystalline basement mostly overlain by Meso to Neoproterozoic sediments in its western part (Figure S1). The craton is bounded by Neoproterozoic marginal fold belts (Figure S1). The eastern part of the craton, where most of the metamorphic rocks are exposed, is subdivided into four major geological units: three Archean blocks (Gavião, Jequié and Serrinha) and two Paleoproterozoic belts: the Itabuna-Salvador-Curaçá Orogen (ISCO) and the Salvador-Esplanada belt (SEB) (Figure S1) (Barbosa & Sabaté, 2004, see references therein). The southernmost part of the Salvador-Esplanada belt, where this study has been conducted, trends broadly North-East and consists mostly of mafic to felsic granulites and migmatites.

2.2. Farol da Barra: metamorphism and age constraints

In the Salvador da Bahia city, high grade metamorphic and magmatic rocks of the SEB are exposed in a horst that is bound on the western side by the Recôncavo sedimentary basin and on the eastern side by the Atlantic coastal margin. The studied area is located at the Barra lighthouse (Farol da Barra; 13°00'41"S; 38°31'57"W, Figure 1a). Four distinct lithologies are identified (Souza Barbosa & Gomes, 2010; Souza-Oliveira et al., 2014) (Figure 1a): (1) orthopyroxene-bearing granulites that constitute most of the basement of the city of Salvador da Bahia and are interpreted to be derived from late Archean tonalitic magmatic rocks (2) garnet-bearing granulites and sapphirine-bearing Al-Mg granulites interpreted as meta-sediments (3) granulitized ultramafic and mafic rocks that occur as centimeter to meter-scale boudins within the paraderived granulites; and (4) monzonitic to syenitic intrusives dykes, oriented ~N10° (Figure 1a), that are either deformed or undeformed with sharp intrusive contacts.

Metamorphic conditions have been estimated at 0.75-0.9 GPa and 840-900°C in the sapphirine-bearing granulites (Fujimori, 1988). The age of the granulitic metamorphism has been

constrained by SHRIMP U-Pb dating at 2089 ± 11 Ma on zircon overgrowths from the orthopyroxene-bearing granulites (Da Silva, McNaughton, 1997). On the same samples, zircon cores yielded an age of 2561 ± 7 Ma interpreted as the crystallization age of the protolith magmatic rocks. The later syenitic to monzonitic magmatism has been dated by Pb-Pb evaporation on zircon at 2064 ± 6 Ma (Souza et al., 2010).

2.3. Farol da Barra: structural relationships

The Barra lighthouse outcrop is characterized by a complex ductile finite strain pattern that results from the superposition of two main phases of deformation (D_1 and D_2) (Figure 1b). The overall geometry consists of meter to decameter lenses, in which D_1 structures are best preserved, surrounded by D_2 ~East-West striking high strain zones (Figures 1b and S2). The first deformation phase (D_1) is characterized by a gently dipping gneissic foliation (S_1) that strikes NE-SW (Figure 1b and S2). This foliation is associated with isoclinal folds with axial planes parallel to S_1 (Figure 1b). The S_1 foliation bears a sub-horizontal L_1 stretching and mineral lineation plunging 0-20°, marked by the preferred orientation of feldspars, quartz ribbons, mafic mineral and elongated ultramafic to mafic boudins. The second deformation phase (D_2) is characterized by heterogeneous deformation that progressively steepens and transposes the previous D_1 fabric along upright D_2 folds and steeply dipping high strain zones (> 55°) that forms an anastomosing network of conjugated shear zones trending approximately east-west (Figures 1b and S2). An L_2 lineation is defined by stretched quartz, feldspars and by the preferred orientation of biotite with a moderate plunge of 10 to 35° towards the NE.

Kinematic analysis in the low D_2 strain domains show that the two sets of ductile conjugate shear zones consist of a dominant 108/72SSW dextral shear zone and minor sinistral 021/79ESE shear zones (Figure S2). This pattern of D_2 finite strain is consistent with a NNW-SSE shortening and a bulk dextral sense of shear. The NW-SE cross-section from the Santa Maria Forte towards the Cristo hill (Figure 1b) shows that the studied area (the Barra lighthouse) corresponds to a major localized D_2 high strain zone within a preserved D_1 low strain domain characterized by gently dipping foliation. Whereas the D_1 domains (Santa Maria fort, Hispaniola hospital, and

198 Cristo Hill) consist mainly of orthopyroxene-bearing granulites, the Barra lighthouse D_2 high
199 strain zone is characterized by the abundance of garnet-bearing granulite. This apparent
200 relationship between deformation and lithology is beyond the scope of this contribution and will
201 not be
202 discussed further.
203
204

205 **3. TEXTURAL AND MINERALOGICAL CHARACTERISATION**

206 **3.1. Outcrop and sample descriptions**

207 The studied sample is located in a S_2 high strain zone that surrounds a large decametric
208 lense of low strain rocks where an earlier fabric (S_1) is preserved (Figure 1). The S_2 granulite-
209 grade gneissic foliation is steeply dipping (072/80S) and contains a gently plunging mineral
210 lineation (09—>075) defined by the preferred orientation of biotite and sillimanite. The gneissic
211 foliation is marked by a compositional banding with centimer-wide quartzo-feldspathic
212 leucosomes in a garnet-bearing granulite (Figure 2a). Leucosomes are usually less than a three
213 centimeters in width and are systematically surrounded by a centimeter thick dark and coarse-
214 grained quartz-undersaturated selvage developed at the expense of the surrounding garnet-
215 bearing granulite (Figure 2b).
216 The studied sample 06SB06 encompasses the three lithologies described above: the host
217 quartz-saturated granulite, a 1 cm-wide quartz-undersaturated selvage and a thin leucosome
218 (Figure 2b). The peak-metamorphic assemblage of the quartz-saturated granulite consists of
219 garnet, sillimanite, plagioclase, biotite, quartz and K-feldspar (Figure 3a). Garnet is interpreted
220 as a peritectic phase produced during biotite dehydration melting via the reaction:
221 biotite + sillimanite + plagioclase + quartz ± K-feldspar = garnet + melt (1)
222 Spinel is locally observed in the matrix but it is always surrounded by a thin corona of sillimanite
223 and it is never in contact with quartz. The preferred orientation of large sillimanite blades (up
224 to 5 mm), K-feldspar and biotite, that occurs either as small flakes or large resorbed grains,

defines the main S_2 foliation observed at the outcrop scale. Garnet contains numerous quartz inclusions and polyphase aggregates of plagioclase + quartz with minor biotite inclusions that all show a preferred orientation at high angle with respect to the S_2 foliation (Figure 3a). This alignment is interpreted as a relict of the former shallow dipping S_1 foliation. Peak metamorphic garnet in contact with sillimanite is partially resorbed and surrounded by a moat of retrograde cordierite (Figure 3b), consistent with the classic reaction

garnet + sillimanite + quartz = cordierite ± melt ± ilm (2)

which proceeds during decompression and/or cooling.

The selvage, in direct contact with the leucosome, is composed of the same peak metamorphic assemblage, consisting of prismatic sillimanite, plagioclase, garnet, biotite and K-feldspar, except it lacks quartz. Biotite is more abundant than in the quartz-saturated granulite. Garnet cores contain numerous quartz inclusions, in association with plagioclase, suggesting that the onset of partial melting and crystallization of peritectic garnet occurred under quartz-saturated conditions. Garnet porphyroclasts are partially broken-down into cordierite and sillimanite is strongly resorbed and replaced by cordierite + spinel symplectites (Figure 3c) via the reaction

sillimanite + garnet ± melt ± biotite = spinel + cordierite (3)

The leucosome consists mainly of quartz and thin elongated K-feldspar ribbons. Plagioclase is very rare and occurs as late myrmekite intergrowths next to K-feldspar.

Mineral compositions are available in Dataset S1. Biotite has XMg of 0.67-0.69 and 0.71-0.73 for the small flakes and large grains respectively, with a constant Ti content of 0.25 to 0.30 pfu. Plagioclase in the matrix has a variable range in anorthite content from 0.43 to 0.52. Spinel is very homogeneous in composition with a XMg of 0.31. Garnet compositions are described in Section 4.

3.2. Evolution of garnet morphology and inclusions

One of the most conspicuous observations is the evolution of garnet size, distribution of

252 inclusions and composition across the quartz-undersaturated selvage and the granulite
253 perpendicular to the gneissic layering. Although no quantitative textural analysis has been
254 conducted, it appears that garnet grain size decreases and the number of garnet grains increases
255 away from the leucosome, with the biggest garnet grains observed in the quartz-undersaturated
256 selvage (Figures 4 and 5). Furthermore, the amount, shape and composition of inclusions in
257 garnet varies greatly and continuously across the gneissic foliation. To describe this evolution,
258 seven garnets (A to G) were selected (see location in Figure 4).
259 In the quartz-undersaturated selvage, most garnets contain a few rounded inclusions of
260 quartz in their core (garnet A, Figure 5a). Away from the leucosome, but still in the selvage, the
261 largest garnet porphyroblast (b) contains in its core a small polymineralic inclusion, that consists
262 of plagioclase and quartz, surrounded by rounded isolated quartz inclusions (Figure 5b).
263 Inclusion-rich garnet cores are surrounded by a large rim free of inclusions except for numerous
264 and homogeneously distributed crystallized granitic melt inclusions that are less than 20 microns
265 in diameter (Figures 5a-b and 6). The inclusions have been identified as crystallized melt based
266 on the main microstructural criteria summarized in Cesare, Acosta-Vigil, Bartoli & Ferrero (2015)
267 : (1) the development of a perfect negative crystal shape (Figure 6a); (2) its polycrystalline
268 nature that consists of biotite, plagioclase, quartz and apatite for the most common phases
269 (nanogranitoids) (Figure 6b-c); and (3) the development of cracks (decrepitation) during
270 decompression filled with minerals similar to those in the melt inclusion(Figure S6). The
271 presence of these crystallized melt inclusions attest to the growth of the garnet rim in the
272 presence of melt.
273 In the quartz-saturated granulite, the abundance of polymineralic inclusions of
274 plagioclase and quartz observed in garnets increases away from the leucosome (Figures 4 and 5c-
275 g). The garnet core, defined as the garnet containing plagioclase-quartz polymineralic inclusions
276 surrounded by isolated quartz grains can be as large as 1mm and represent up to 50% of the
277 garnet volume. Polymineralic inclusions have rounded (Figure 5c-d-f) to very irregular shapes
278 with straight boundaries (Figure 5e). These facets are inferred to be parallel to crystallographic
279 orientations of the garnet host and result from post-entrapment readjustment of the inclusion

and host by dissolution-reprecipitation processes (e.g. Frezotti, 2001). Plagioclase in the polymineralic inclusions are chemically zoned with a composition varying almost continuously from pure anorthite $An_{95}Ab_{05}$ to $An_{58}Ab_{41}$. Highest amounts of albite are measured in the vicinity of rounded quartz inclusions within plagioclase and the garnet host (Figure S3). All garnets have an inclusion-free rim without any melt-inclusions, as for the garnet located in the quartz-undersaturated selvage (Figure 5). This difference in the ability for garnet rims to entrap melt inclusions may be related to a slowdown of radial growth rate as garnet continuously grows.

X-ray computed microtomography and sequential cuts through a single garnet crystal has been performed to highlight the volume, shape and potential connectivity of the polyphased inclusions with the matrix. The selected garnet is located in the quartz-saturated granulite where the amount of polyphase quartz-plagioclase is most abundant. The X-ray tomography reveals the very irregular shape of the polyphased inclusions as well as the “spongy” texture of the garnet core (Figure 7). Although all thin-section photomicrographs of garnet presented in Figure 5 suggest that polyphase inclusions are completely enclosed in the garnet, the 2D cuts rather suggest that they are connected to the matrix through small pathways (Figure 7d-f and Movie S1).

3.3. Microtextures in the quartz-undersaturated selvage

Microtextures in the quartz-undersaturated selvage have been revealed using a cold cathode cathodoluminescence detector on an optical microscope. The matrix consists mainly of K-feldspar grains (in blue in the CL images) that form a fine-grained mosaic texture with straight boundaries and triple junctions at 120° (Figure 8a-b). K-feldspar is characterized by a core with fine-grained perthite textures surrounded by a K-feldspar rim (Figure 8a). These boundaries are coated with thin plagioclase films or elongated grains (brown color in Figure 8a-b) that can be connected to form a branching array. Terminations of the films and elongated grains are characterized by small dihedral angles (< 20°). The connection of these films also leads to the formation of plagioclase pools along grain boundaries (Figure 8a-b) or at K-feldspar triple

junctions. Where plagioclase films are abundant, K-feldspar grains show very irregular resorbed grain boundaries (Figure 8b) and plagioclase films are connected to myrmekites pools (Figure 8a-b). Finally, a large plagioclase (± quartz) moat surrounds sillimanite and garnet porphyroblasts (Figure 8b).

4. GARNET COMPOSITION

To investigate the link between the textural and mineralogical features of melt-rock interaction and their compositional characteristics, major element data from multiple garnet grains were obtained by EMPA, and trace element data by LA-ICP-MS. X-ray maps and linear spot traverses were acquired to reveal the evolution of major element zoning patterns across the quartz-undersaturated selvage and granulite. Trace element mapping was performed to better inform the paragenetic context, particularly with regard to accessory minerals, and evaluate the record of geochemical mobility during garnet growth and dissolution. Major and trace element data are provided in Datasets S1 and S2, respectively, and presented in Figures 9, 10, 11, 12 and 13. . Raw trace element maps from which the profiles were extracted are available as ".csv" text file images (Dataset S3-S5). LA-ICP-MS analytical methods are provided in Appendix S1.

4.1. Major element zoning

Garnets are almandine – pyrope – grossular solid solutions with minor amounts of spessartine (< 0.015) (Dataset S1). All garnets are zoned and their composition varies with respect to their location and distance from the leucosome. In the quartz-undersaturated selvage, a polymineralic inclusion-free garnet porphyroblast in direct contact with the leucosome (Garnet A; Figure 5a) is characterized by bell-shaped zoning in grossular, with a maximum content of 0.12 in the core that decreases continuously towards the rims down to 0.03 (Figure 9a). Almandine and pyrope content increase towards the rim from 0.56 to 0.61 and 0.30 to 0.35, respectively, which results in a constant XMg [=Mg/(Fe+Mg)] of 0.34-0.35. Garnet B has equivalent zoning, except that close to the polymineralic inclusions, grossular content decreases

from a 700 μm wide and uniform plateau at 0.12 down to 0.08 (Figure 9b). This decrease in grossular content is mimicked by an increase of XMg from 0.35 to 0.38. It is noteworthy that the depleted grossular core also corresponds to the domain containing smoothed and rounded inclusions of quartz (light gray area in Figure 9b). The outer rim of Garnet B is characterized by grossular content and XMg value of 0.03 and ~0.35-0.36, respectively (Figure 9b). The resorbed outer left rim, in contact with cordierite and biotite, shows a sharp decrease in XMg down to 0.28 over a distance not greater than 100 μm (Figure 5b and 9b).

Garnets from the quartz-saturated granulite (Garnets C-G) show zoning profiles comparable in shape to Garnet B from the quartz-undersaturated selvage, except that the endmember modal abundances are significantly different (compare Figure 9b and Figure 9c-g). Garnet cores in direct contact with the polymineralic inclusions are characterized by low grossular values (0.03-0.04) that are similar in composition to garnet rims in contact with the matrix. Grossular content then increases towards the rim to a maximum value that is systematically located at the transition between the inclusion-bearing and inclusion-free garnet (Figure 9c-g). The maximum grossular content varies from grain to grain, from 0.095 (Garnet E) down to 0.045 (Garnet F). Finally, the inclusion-free rims show a decrease in grossular content towards the matrix to a minimum value of 0.03, equivalent to the core compositions. XMg ratio profiles for all samples are relatively flat, with values evolving from 0.36-0.37 (Garnet C) to 0.41-0.44 (Garnet G) with increasing distance from the leucosome. The smallest garnet grain analyzed (Garnet F) does not follow this trend, showing a lower XMg value of 0.36 and a near-constant grossular content of 0.03-0.04. Garnet E profile shows on its left side a sharp decrease in XMg from 0.40 to 0.36, over a distance less than 100 μm, that is interpreted as late Fe-Mg exchange during partial garnet breakdown into cordierite, comparable to Garnet B.

4.2. Trace element zoning

Similar to their major element characteristics, the analyzed garnets show significant

variations in trace element composition and zoning patterns depending on their location with respect to the leucosome. We will focus on Garnets A and B, located in the quartz-undersaturated selvage, and Garnet G, located in the quartz-present host granulite.

Garnet A is located directly adjacent to the leucosome, and contains the least inclusions in its core except for a few rounded quartz grains. Figures 10a, 11 and Figure S4 illustrate the key features of the trace element zoning. Y, Zr, V and heavy rare-earth elements (HREEs), from Dy to Lu, show a symmetrical bell-shaped profile without sharp discontinuities except for an abrupt increase at the rim. In contrast, light rare-earth elements (LREEs), from La to Gd, show a bowl-shaped zoning profile with a broad flat core that is mimicked by Li, P and Sc. Notably, the radial positions of broad peaks along the zoning profile are correlated for all REEs and Y (Figure 11), and there is no difference in gradient with decreasing atomic number.

Garnet B is the largest analyzed grain, with a small polyphase plagioclase + quartz inclusion in its core. It is located a few millimeters from Garnet A within the quartz-undersaturated selvage but further displaced from the leucosome. Trace element map and profile are shown in Figure 10b, 12 and S4. Its zoning pattern shows the same symmetrical bell-shape profile for Y, Zr and the heaviest HREE (from Yb to Er), but with elevated concentrations compared to Garnet A (e.g. Y ~360 vs 270 ppm; Yb ~75 vs 45 and Lu ~15 vs 6 ppm). In contrast, rim compositions are strictly identical for all elements in both samples (compare Figures 11 and 12 and S4). Because Garnets A and B are located in the same petrographic setting, we suggest that the difference in absolute concentrations reflects a sectioning effect (i.e. Garnet A is not sectioned through its core) rather than a geological process. The outer rim of Garnet B is characterized by a sharp increase in Y, Zr and HREEs, and LREEs and P have the same overall bowl-shaped zoning as Garnet A despite a more irregular profile that includes several narrow peaks. Concentrations in La, Ce and P are significantly enriched next to the polyphase inclusion and the matrix on the left side of the profile (Figure 12). The major difference in comparison to Garnet A corresponds to a broad depletion in Dy, Ho and Tb adjacent to the polyphase inclusion located at the garnet core. This feature closely matches the grossular zoning profile (Figure 9b),

and corresponds to the domain containing rounded inclusions of quartz.

Garnet G is derived from the quartz-present host granulite and is located furthest from the leucosome (Figures 4 and 5). It is the smallest analyzed grain and contains a large irregular polyphase inclusion in its core. Trace element map and profile are shown in Figure 10c, 13 and S4. Y and HREEs, from Lu to Tb, show a broad bell-shaped profile, but with maximum concentrations on average two to three times lower than the larger Garnets A and B (Figure 13). In contrast, rim compositions for all elements are once again similar for all samples. La, Ce and P show bowl-shaped profiles with a large flat core surrounded by an enriched rim. Sm (and to a lesser extent Gd) are no longer characterized by a typical bowl-shaped profile but rather mimic the grossular zoning, with a depleted core next to the polyphase inclusion (Figure 13). This similarity continues along the profile, with an identical location for the maximum Sm concentration and a core composition adjacent to the polyphase inclusion that is equivalent to the rim composition (2 to 3 ppm on average; Figure 13).

5. PETROLOGICAL MODELING

We use computed phase diagram sections to constrain (1) the pressure and temperature of garnet nucleation and growth, partial melting, and retrogression; and (2) the most likely processes responsible for the formation of the quartz-undersaturated selvage. For this purpose, the model system Na_2O-CaO-K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O was chosen to calculate phase relationships using Perple_X 6.6.6 software (Connolly, 2005), with the thermodynamic database of (Holland & Powell (1998), as revised in 2002). TiO_2 and Fe_2O_3 where not considered in the modeling because (1) the bulk rock content of TiO_2 is less than 0.6 wt%; and (2) there is no Fe^{3+}-bearing phase like hematite or magnetite and the amount of Fe^{3+} in garnet based on structural formulae is negligible. Solution models and end-member phases considered in the modeling are listed in Table S1.

413 **5.1. P-T conditions of garnet nucleation and growth**

414 Deciphering the P-T conditions of the early garnet growth and prograde path relies
415 essentially on the observation of garnet inclusions and the valid interpretation of garnet
416 composition and zoning. Garnet cores are characterized by the occurrence of quartz and
417 polyphase plagioclase-quartz inclusions, whereas the inner rim of the largest garnet grains show
418 abundant crystallized melt inclusions. We therefore suggest that the onset of garnet growth may
419 have occurred under sub-solidus conditions.

420 Garnet core compositions are typically used to retrieve the approximate P-T conditions of
421 garnet nucleation. However we will show later that major and trace element zoning patterns
422 and more particularly garnet core compositions have been modified, most likely as a result of
423 post-growth re-equilbration during partial melting and retrogression. The biggest garnets located
424 in the quartz under-saturated selvage (garnet A and B, Figure 4-5) show the least modified
425 zoning profile, with typical bell-shape zoning in grossular (Figure 9a,b) and trace elements
426 (Figure 11-12). Although these large garnets A and B are located in the quartz-undersaturated
427 selvage, the presence of quartz inclusions within their cores suggests that the onset of garnet
428 growth occurred under quartz-saturated conditions. We therefore suggest that the loss of SiO_2
429 and the formation of the quartz-undersaturated layer is a post-garnet growth process. Hence, to
430 retrieve the P-T conditions of early garnet growth and constrain the prograde path, we have
431 computed a P-T phase diagram section with a XRF bulk composition corresponding to the quartz-
432 saturated domain composition (Table 1 and Figure 14). The phase diagram section has been
433 contoured for grossular content, XMg (= MgO/MgO+FeO) in garnet and garnet modes (Figure 14).

434 The amount of water is known to be a critical variable when modeling phase relations in
435 melt-bearing systems (e.g. White et al., 2001). A classic strategy to estimate the amount of
436 water in melt-bearing systems consists of adding enough water to the system such that the
437 solidus is water-saturated. However, if we follow this approach, high-grossular garnet core
438 compositions cannot be reproduced. Therefore, the system was kept water-undersaturated, such
439 that measured garnet core compositions (i.e. the highest grossular values) are predictable, and

the amount of major rock-forming phases are consistent with observed mineral modes. The amount of water was adjusted and fixed at 1.67 mol% (0.025 mol or 0.46 wt%). With this low water condition, partial melting was restricted to temperatures higher than ~750°C (Figure 14)

The maximum grossular content of ~0.12, coupled with the corresponding XMg (0.35-0.38), allow estimating the minimum P-T conditions of garnet growth at ~1.2 GPa, 675°C (black circles with letters in Figure 14). This corresponds to sub-solidus conditions where garnet is in equilibrium with plagioclase, biotite, kyanite and muscovite. Although these last two phases have never been observed as inclusions in garnet, the predicted plagioclase composition (An_{76}-Ab_{23}) is consistent with the high anorthite compositions measured in plagioclase inclusions. Furthermore, melt-inclusions are absent in the high grossular cores (Figure 5), whereas they are abundant in the low-grossular rims. This observation is consistent with an early garnet nucleation and growth under sub-solidus conditions with peak metamorphism and garnet rim crystallization occurring in melt-present conditions.

In Figure 14, we report the composition of Garnet C to G, located in the quartz-saturated domain, with the highest grossular content and corresponding XMg values (grey circles with letters in Figure 14). The maximum grossular content, preserved in the inner rim at the transition between the inclusion-bearing and inclusion-free domains, varies from grain to grain from 0.095 (Garnet E) down to 0.04 (Garnet F) and XMg from 0.36 (Garnet C) to 0.43 (Garnet G) (Figure 9). The inferred P-T conditions vary from ~1.3 GPa and 720°C to 0.85 GPa and 780°C corresponding approximately to the P-T conditions of garnet nucleation and peak metamorphism / partial melting , respectively (see Section 5.2 below). We suggest that this could reflect the progressive and incomplete re-equilibration of garnet during a prograde (heating/decompression) path from ~1.2 GPa and 675°C down to 0.8 GPa and 790°C. During this P-T evolution minor garnet growth is expected (volume % = 14-16, Figure 14).

465 **5.2. P-T conditions of peak metamorphism, partial melting and retrogression**

466 The computed P-T phase diagram in Figure 14 shows the classic phase relations for
467 partially melted aluminous-rich pelites (e.g. White et al., 2001), with the divariant muscovite-
468 dehydration melting equilibrium at high pressure (1.2 > P > 0.9 GPa) and the biotite-dehydration
469 melting equilibrium that produces garnet and cordierite at lower pressure (0.8 > P > 0.6 GPa).
470 Between these two divariant narrow fields lies a trivariant assemblage with garnet, biotite,
471 sillimanite, K-feldspar, quartz and melt in equilibrium, between 770 and 820°C (Figure 14). This
472 calculated assemblage is consistent with the observed assemblage in the quartz-saturated
473 granulite. Garnet core and rim compositions in direct contact with the polyphased plagioclase-
474 quartz inclusions (ca. 3% grossular and XMg = 0.36-0.44) give consistent P-T conditions of 0.8 ±
475 0.05 GPa and 790 ± 20 °C (white circles with letters in Figure 14), with the predicted XMg of
476 biotite (0.70) consistent with the measured biotite composition. We interpret these estimates to
477 reflect partial melting during the development of the steeply dipping S_2 granulite-grade gneissic
478 foliation. As discussed in Section 7.2, however, the garnet trace element distribution indicates
479 that core compositions may have been affected by post-growth re-equilibration.
480 Retrogression in the quartz-saturated domain is characterized by the local development
481 of cordierite at the expense of garnet and sillimanite (Figure 4b), through reaction (1). This local
482 and partial retrogression is also evidenced by the sharp decrease in XMg from 0.40 to 0.36, at
483 constant grossular content (~0.30) (Figure 9e, outer rim of Garnet E). Figure 14 shows that the
484 development of cordierite and the decrease in XMg, at almost constant grossular content, would
485 require further isothermal decompression at or below 0.7 GPa in the garnet + cordierite +
486 sillimanite + K-feldspar + plagioclase + quartz stability field.
487

488 **5.3 Formation of the quartz-undersaturated selvage via melt-driven metasomatism**

489 In migmatites, the formation of quartz-undersaturated assemblages has been interpreted
490 as characteristics of advance quartz-consuming reactions during partial melting coupled with
491 local melt extraction (Fitzsimons, 1996; Owen, 1991). Alternative models consist of producing

492 the quartz-depleted selvage by small-scale silica metasomatism between the host rock and a
493 quartz vein (Penniston-Dorland & Ferry, 2008) or a silica-rich leucosome formed after melt
494 segregation and transport (Dunkley, Clarke & Harley, 1999). In the later case, selvage formation
495 is a post-anatectic process rather than being directly related to partial melting of the host-rock
496 (Lin & Sawyer, 2019). In the following section, we model and show that element exchange
497 (diffusion-metasomatism) between the segregated melt (leucosome) and the host granulite is
498 likely to be responsible for the formation of the quartz-depleted selvage during post-peak
499 decompression.

500 Following the approach of White and Powell (2010), we investigate through phase
501 equilibria modeling the melt-driven metasomatism and more particularly the role of diffusion,
502 between melt-rich domains (leucosome) and the host granulite, on the formation of the selvage.
503 Our conceptual model is similar to Lin & Sawyer (2019) and requires a first stage of partial
504 melting and melt segregation to produce two subsystems corresponding to the quartz-saturated
505 domain (~residue) and the melt domain. At the P-T conditions of partial melting and melt
506 segregation (i.e. 0.8 GPa and 790°C), chemical potentials are the same in the solid phases and
507 the melt of both domains, if thermodynamic equilibrium is maintained. The second stage
508 corresponds to decompression into the cordierite-bearing stability field below 0.7 GPa. As
509 pressure decreases, chemical potential evolve independently in both subsystems. Therefore,
510 diffusion of components is driven by the chemical potential gradient established at the interface
511 between the quartz-saturated residue and the leucosome.

512 In order to determine the direction of diffusion, we have computed the chemical
513 potentials of H_2O, SiO_2, CaO and K_2O for the quartz-saturated and melt domains along an
514 isothermal decompression path from 0.8 to 0.5 GPa at 790°C (Figure 15). The chemical
515 potentials in the melt domain were determined using the chemical composition of melt
516 produced at 0.8 GPa and 790°C (Table 1). Chemical potential of the selected components were
517 computed separately for each sub-systems (segregated melt and residue) by assuming that
518 during decompression these two sub-systems are closed and chemically isolated from each other
519 (Figure 15). This implies that there is no interaction or mass transfer between the two

subsystems. This ideal chemical isolation model is in a strict sense impossible because the two sub-systems are physically in contact and therefore chemical interactions are expected at some scale and chemical potential will continuously evolve with ongoing decompression due to diffusive mass transfer (White & Powell, 2010). However, our approach can be used at first order to determine the direction of transport of the four selected species if chemical interaction at the interface is permitted. During decompression, the chemical potentials of H_2O, CaO, K_2O and Na_2O (Na_2O not shown in Figure 15) become higher in the melt segregated domain (leucosome) than in the residue. In contrast, the chemical potential of SiO_2 is lower in the melt than in the residue. This suggests that species such as H_2O, CaO, K_2O and Na_2O will diffuse from the melt into the host residue whereas SiO_2 is transferred from the host residue into the adjacent melt domain.

To model the effect of metasomatism and pressure on phase relations, a P-X phase diagram section was computed at 790°C (Figure 16). The initial amounts of CaO and Na_2O are very low (< 1.3 and 0.6 wt%, respectively) and do not significantly influence the phase relations. Therefore, variations in Na_2O and CaO content are not considered. The bulk composition for X = 0 corresponds the quartz-saturated host-rock composition prior to any mass transfer. The bulk composition for X=1 is obtained assuming a gain in H_2O of 200% (H_2O = 0.075 mol) and a SiO_2 loss of 55% (SiO_2 = 0.342 mol). These values are arbitrary. Bulk compositions used are provided in Table 1.

Figure 16 shows the location of the two main low variance (V=2) retrogression equilibria that have been observed in the quartz-saturated domain and quartz-absent selvage: Grt + Sil + Qz ± Bt = Crd + L (2) and Grt + Sil ± Bt = Crd + Spl + L (3) at 0.72 GPa and 0.55 GPa respectively. These divariant equilibria together with their related trivariant assemblage are used to locate the quartz-out, cordierite-in and spinel-in boundaries (Figure 16). The formation of selvage assemblage (Crd + Spl + Sil + L ± Grt/Bt) requires a decompression below 0.55 GPa and a bulk composition with X ranging from ~0.65 to 0.8. Taking a value of X = 0.7, mass transfer required to produce the selvage from the host quartz-saturated granulite corresponds to a relative gain of

about 140 % of H_2O coupled with a relative loss of 47% of SiO_2. The P-X phase diagram is also contoured for garnet mode (Figure 16). As expected, decompression is associated with garnet breakdown, but at pressures above the cordierite-in boundary (P > 0.72 GPa), mass transfer (SiO_2 loss coupled with H_2O gain) induces a slight increase in garnet mode, from 12 to 17 vol%. This mineralogical evolution is consistent with the observation of a higher modal abundance of garnet in the metasomatic selvage with respect to the host granulite.

Based on the estimation of mass transfer required to produce the quartz-undersaturated selvage, a P-T phase diagram section has been computed with an estimated selvage composition (Figure 17 and table 1). This composition corresponds to X = 0.70 in Figure 16. Figure 17 shows the location in a P-T space of the two main low-variance retrogression reactions (2) and (3) and the position of the quartz-out, cordierite-in and spinel-in lines. Once again, the selvage formation is consistent with a decompression from about 0.8 GPa down to 0.5 GPa at temperatures greater than 750°C.

6. U-TH-PB MONAZITE AND ZIRCON GEOCHRONOLOGY

Monazite and zircon geochronology were acquired to establish a temporal framework for melt-rock interactions and the relationship of garnet growth and dissolution to the accessory mineral evolution. Chemical zoning in monazite and zircon were first characterised via X-ray mapping and cathodoluminescence respectively. In situ U–Th-Pb monazite and zircon ages were then acquired by laser ablation inductively coupled plasma-mass spectrometry (LA-ICP-MS). Sample preparation and operational procedures for all techniques are described in Hurai, Paquette, Huraiová & Kronečný (2010) and Paquette et al. (2014) and presented in Appendix S2. U-Th-Pb geochronological data are provided in Dataset S6.

572 **6.1. Textural features and dates**

573 Monazite is abundant in both quartz saturated and undersaturated domains but is totally
574 absent in the leucosome. The analyzed monazites range in size from 50 to 250 μm and occur in
575 the matrix, at grain boundaries and included in sillimanite and plagioclase (M1-2-13), in the
576 vicinity of garnet and within the retrograde cordierite moat (M3-6-4-8-9-10-11-12) (Figure 18a).
577 Monazite grains M3, M6 and M12, located in cordierite moats, have an unusual worm-like shape
578 that mimics the embayed garnet rim (Figure 18c). Only one grain (M7) was found included in a
579 garnet rim.

580 All monazite grains are chemically homogeneous (Y-poor) (Figure 18b,c) except for two
581 grains (M9 and M10) that show a subtle zoning with high Th domains. Grains located in the
582 cordierite moat show discrete and discontinuous micron-scale Y-rich rims (Figure 18c) whereas
583 those included in other phases are devoid of such overgrowths (Figure 18b). These observations
584 suggest that the crystallization of the low Y grains might precede or be coeval with the peak
585 assemblage garnet (rim), sillimanite, biotite, plagioclase, K-feldspar ± quartz. The crystallization
586 of discrete Y-rich monazite overgrowths in the vicinity of garnet porphyroblasts partially
587 retrogressed into cordierite has been previously interpreted as an indicator of accessory phase
588 growth during garnet breakdown (Mahan et al., 2006). We suggest that Y overgrowths are also
589 contemporaneous with cordierite crystallization and selvage formation.

590 Ten homogeneous Y-poor grains were analyzed for a total of 39 analyses (Dataset S6). The
591 Y-rich overgrowths were not analyzed due to their small size in order to avoid mixing during
592 ablation. In a $^{206}Pb/^{238}U$ versus $^{208}Pb/^{232}Th$ diagram all analyses are concordant or sub-concordant
593 (Figure 19a). Excluding six analyses (see Dataset S6) gives a concordia age of 2061± 6 Ma
594 (MSWD(C+E) = 1.3). The weighted mean of $^{208}Pb/^{232}Th$ dates gives an age of 2069 ± 8 Ma (MSWD =
595 1.6) (Figure 19b). The $^{208}Pb/^{232}Th$ dates show no systematic variation with textural location (see
596 Figure 18a and Dataset S6), and more specifically, monazite included in garnet (M7) is not
597 statistically different from matrix grains (Figure 19). The date of 2.06 Ga is interpreted as the
598 age of partial melting at 0.8 ± 0.05 GPa and 790 ± 20 °C, before decompression responsible for

599 partial garnet breakdown and crystallization of small Y-rich overgrowths.

600 Zircons are rare and do not exceed 50 µm in diameter. They are translucent with a
601 rounded shape typical of zircons recrystallized under granulite facies conditions. Fourteen
602 analyses were performed on fourteen grains (Dataset S6). They do not show significant zoning in
603 cathodoluminescence. A first group of 7 analyses are concordant and gives a concordia age of
604 2072 ± 7 Ma (MSWD(C+E) = 2.3) (Figure 19c). A second group of 4 analysis are discordant and
605 when plotted together with the previous 7 analysis, it defines a discordia with an upper
606 intercept at 2073 ± 11 Ma (MSWD = 2.0). The last group, consists of 4 analyses that do not match
607 the previous tow identified clusters (white ellipses in Figure 19), with $^{207}Pb/^{206}Pb$ dates that
608 range from 2.07 to 2.33 Ga and one concordant analysis at 2192 ± 15 Ma. The 2.07 Ga date is
609 similar to that obtained for monazite and is interpreted as the age of partial melting. The
610 remaining three analyses are interpreted as inherited ages.

611

612 **7. DISCUSSION**

613 Petrological and micro-textural analysis carried out across the interface between the
614 leucosome and the host-granulite shows a systematic and consistent evolution in mineral
615 paragenesis, micro-textures, garnet grain size and composition (major and trace element) with
616 the distance from the leucosome. The studied sample is therefore used to discuss small-scale
617 melt-rock interaction processes. In this section, we will first summarize the petrological model
618 of formation of the migmatite and more particularly the quartz-undersaturated selvage at the
619 interface between the segregated melt (leucosome) and the partially melted host granulite.
620 Based on this petrological evolution, we will discuss the significance of major and trace element
621 zonation observed in garnet.

622

623 **7.1. Petrological model of migmatite and quartz-undersaturated selvage formation through**
624 **diffusion metasomatism**

625 The phase relation modeling performed suggests that the onset of garnet crystallization
626 occurred under subsolidus conditions at high pressure (P~ 1.2 GPa) and temperatures of 675 to
627 700°C. These P-T conditions, that were estimated using the maximum grossular content of
628 garnet cores and anorthite content of plagioclase inclusions, are consistent with a steady state
629 geotherm considering average crustal thermal parameters (thermal conductivity k = 3 $W.m^{-1}.K^{-1}$,
630 heat production A = 0.75 $\mu W.m^{-3}$, a mantle heat flow Q = 30 mW^{-2}, a density ρ = 2.7 $kg.m^{-3}$) at a
631 depth of 45 km (1.2 GPa). We suggest that the gently dipping gneissic foliation (S_1) that trends
632 NE-SW (Figures 2b and S1) may be occurred at to these conditions and may correspond to a
633 crustal thickening event. This interpretation is also supported by the observation of quartz and
634 plagioclase inclusions trails, defining a S1 foliation, in the high-grossular garnet cores (Figure
635 3a).

636 Partial melting occurred at 0.8 GPa and 790°C at ~2.06-2.07 Ga. The former presence of
637 melt at peak metamorphic conditions can reliably be inferred from the occurrence of peritectic
638 garnet, produced by biotite-dehydration melting (1) (Figures 4-5) and the presence of
639 crystallized melt inclusions within the garnet (Figure 6). Interstitial elongated films along grains
640 boundaries and pools at the triple junction (Figure 8) are alternative criteria diagnostic of the
641 former presence of melt and melt movement at the grain scale (Holness & Sawyer, 2008; Sawyer,
642 2001; Stuart, Piazolo & Daczko, 2018; Vernon, 2011). The interstitial plagioclase may represent
643 the plagioclase component crystallized from the melt (Hasalová, Schulmann, Lexa, Štípská &
644 Hroda, 2008; Stuart et al., 2018). The corroded K-feldspar grains and the crystallization of
645 plagioclase and myrmekite (figure 8) are interpreted as the result of K-feldspar dissolution
646 during the interaction between the host rock and a migrating melt (Hasalová et al., 2008). We
647 suggest that the connection between the leucosome and the host-granulite via the grain
648 boundary melt array favored efficient small-scale mass transfer in and out of the host-granulite
649 to produce the quartz-undersaturated selvage.

Thermodynamic modeling shows that decompression from 0.8 to 0.5 GPa at 790°C coupled with melt segregation are responsible for the establishment of chemical potential gradients between the leucosome and the host-granulite. Chemical potential gradients drive diffusive metasomatism of species between the two reservoirs and the formation of the quartz-undersaturated selvage at the interface. The modeling suggests that, during post-peak decompression from 0.8 to ~0.5 GPa at 790°C, species like H_2O, CaO and Na_2O will be transferred from the leucosome to the host-rock while SiO_2 had an opposite diffusion direction, going from the host-rock to the leucosome. Phase diagrams in figure 16 and 17 show that mass transfer coupled with decompression resulted in the partial transformation of the quartz-saturated peak metamorphic assemblages (Grt, Bt, Sil, Qz + L) into a quartz-undersaturated assemblage with cordierite and spinel (see location of Qz-out, Crd-in and Spl in Figure 16). Formation of the quartz-undersaturated selvage via melt-driven metasomatism (ie. SiO_2 loss), is well supported by the absence of quartz in the matrix and the observation of quartz only as inclusions in garnet cores. This observation rules out the possibility that the gneissic layering and more particularly the quartz-absent selvage is inherited from the sedimentary protolith. The phase diagram shows that further mass transfer and decompression below 0.5 GPa could result in the formation of corundum-bearing assemblage.

Several other petrological and micro-textural observations provide support for the modeled mass transfer direction and the formation of the selvage:

(1) The quartz-undersaturated selvage, where local mass-transfer is inferred as the dominant process, is characterized by larger garnet grain sizes. This is consistent with modeled garnet modes in Figure 16, that show an isobaric and isothermal increase in garnet abundance at 0.8 GPa, only due to mass transfer (SiO_2 gain and H_2O loss).

(2) Diffusion of water from the melt into the host-granulite will favor the crystallization of anhydrous products in the melt, producing almost an anhydrous leucosome, while the adjacent host granulite is hydrated, as demonstrated by the slight enrichment of the selvage in hydrous-phases like biotite and cordierite. This observation is very consistent with results from

White and Powell (2010) who also predicted that the diffusion of H_2O into the residue will be responsible for the formation of anhydrous leucosomes during an isobaric cooling under granulite facies conditions.

(3) Diffusion of other mobile species like CaO, Na_2O and K_2O, from the leucosome into the selvage is indirectly supported by the mineralogical composition of the leucosome that consists mostly of quartz with very minor K-feldspar and almost no plagioclase. It is well known that leucosomes in migmatites do not have the expected minimum granitic composition (Ashworth & McLellan, 1985) due to post-anatectic magmatic differentiation processes. However, following Olsen and Grant (1991), who performed a mass-balance (isocon) analysis on leucosomes, we suggest that the quartz-rich and K-feldspar and plagioclase-poor leucosomes most likely formed by loss of Na_2O and CaO by diffusion.

(4) Diffusion of K_2O into the host-rock is likely to be responsible for the formation of the distinct inclusion-free outer-rim of K-feldspar located in the selvage (Figure 8).

(5) The introduction of a Na_2O/CaO-rich fluid or melt into the selvage, is consistent with the observation of plagioclase films and pools along K-feldspar grain boundaries (Figure 8). The formation of myrmekite in the selvage is also consistent with a fluid or melt mediated Na-Ca replacement of K-feldspar by plagioclase (Yuguchi & Nishiyama, 2008).

Melt segregation and the development of the selvage defines a steeply deeping S_2 gneissic layering that transposes the previous S_1 fabric (Figure 3 and Figure S1). Kinematic analysis of the D_2 high strain is consistent with NNW-SSE shortening and a bulk dextral sense of shear. We conclude that melt transfer and metasomatism may have been enhanced by D2 transpressive deformation.

7.2. Major and trace element behavior during partial melting and retrograde melt-rock interaction

The studied sample preserves mineralogical and textural evidence of prograde partial melting and melt segregation, near-isothermal decompression and melt-driven metasomatism. With respect to other phases, garnet has the tremendous advantage to preserve records of these

various processes via its chemical zoning in major and trace elements, because of the slow rates of intracrystalline diffusion (e.g. Carlson, 2006). However, in order to interpret accurately these zoning patterns in terms of large-scale and long-term geological/geodynamic processes, we have to understand the small-scale processes that control the behavior of major and trace elements during garnet nucleation, growth, breakdown and re-equilibration (George & Gaidies, 2017 and references therein). Although the zoning features varies from garnet to garnet, they show systematic variations and similarities that can be correlated with the P-T-X evolution and petrographic setting. Via a qualitative analysis of zoning profiles, and previous work by others cited below, we suggest these features reflect the superposition of at least three grain-scale processes that control the intra- and intergranular mobility of chemical components (major and trace elements).

Evidence of fast intergranular mobility of elements, including REE, and rock-wide equilibrium

The P-T evolution of the studied sample occurred at high temperature (> 650°C) and in the presence of melt, from peak-metamorphic conditions (0.8 GPa; 790°C) to the conditions of selvage formation (~0.5 GPa; 800°C). Therefore, the high mobility of major and to a lesser extent trace elements is expected. We report below evidence of fast intergranular mobility of elements, including REE, and rock-wide equilibrium.

Rock-wide equilibrium and by extension fast inter-granular transport of major and trace elements during peak metamorphic conditions and subsequent melt-driven metasomatism is best demonstrated using garnet rim compositions. Although the analyzed garnets are located in different petrographic settings (within the quartz-undersaturated selvage or in the host-granulite displaced from the leucosome) and vary markedly in grain size and morphology, their outermost rims share consistent major element (grossular content = 3%; Figure 9) and trace element compositions (Y and REEs; Figure 11-13). This consistency in major element composition of the rims permits an accurate estimation of peak metamorphic conditions at 0.8 GPa and 790°C (Figure 14).

732 The length scale of equilibration during garnet growth, which is related to the degree of
733 mobility of major and trace elements through the intergranular matrix, can be evaluated using
734 the REE zoning pattern (Moore et al., 2013; Skora et al., 2006). In both studies, these authors
735 have shown a dependency of REE distribution on atomic number in large and early nucleating
736 garnets. Such garnets are characterized by pronounced central peaks for Y and HREEs (Lu to Er),
737 central peaks and annular maxima for MREEs (Ho, Dy), and well defined annular maxima for
738 LREEs (Tb to Nd). This distribution is driven by diffusion-limited uptake that evolves during
739 garnet growth. With increasing temperature, intergranular diffusivities increase progressively as
740 garnet grows, but with more rapid diffusion for HREEs compared to LREEs (Moore et al., 2013;
741 Skora et al., 2006). However, this dependency of REE distribution with atomic number is less
742 valid at high temperature. Numerical modeling of garnet zoning along a temperature-time path
743 performed by Moore et al. (2013) demonstrates that a uniform bell-shaped distribution for all
744 REEs is consistent with garnet nucleation and growth at high temperature, whereas at lower
745 temperature a sharp central peak with an annular maximum would be expected (see Figure 19
746 and Figure 20b in Moore et al. (2013)). From these previous studies, we can conclude that a
747 uniform distribution for all REEs is the result of rapid intergranular diffusion that strongly
748 minimizes the development of concentration gradients in the matrix surrounding the growing
749 garnet.

750 All studied garnets are characterized by a bell-shape distribution for Y and REEs, ranging
751 from Lu to Dy (± Tb), with a strong correlation between the radial positions of all peaks. This
752 distribution is consistent with a progressive depletion of the matrix in Y and REEs (Lu-Dy) due to
753 Rayleigh fractionation with an unchanging mineral assemblage (Moore et al., 2013; Otamendi et
754 al., 2002). Although the inferred P-T path in Figure 14 suggests that the onset of garnet growth
755 may have occurred under sub-solidus conditions prior to muscovite dehydration, we instead
756 suggest that the majority of garnet growth occurred via biotite dehydration melting in the
757 trivariant NaCaKFMASH stability field Bio – L – Gt – Kf – sill – pl – q at a temperature greater than
758 ~760°C. The uniform bell-shaped distribution for REEs, ranging from Lu to Dy, is consistent with

759 rapid intergranular diffusivities.

760 All garnet grains are characterized by (1) the absence of progressive outwards migration
761 of REE peak locations with decreasing atomic number; and (2) the lack of a central peak for
762 LREEs between La and Gd. Instead, they show a large LREE-depleted core of constant
763 composition surrounded by an enriched rim. This transition from bell- to bowl-shaped profiles
764 with decreasing atomic number is similar to an example reported by Raimondo et al. (2017) from
765 a metasomatic shear zone in central Australia. Both observations (1) and (2) are once again
766 indicative of fast intergranular mobility and rock-wide equilibrium during garnet growth, without
767 significant differences in diffusivity between HREEs and LREEs. However, we will see below that
768 the bowl-shaped profile could also be related, or at least accentuated, by a post-growth
769 modification.

770 Following Raimondo et al. (2017) and Konrad-Schmolke et al. (2008), we suggest that the
771 REE zoning reflects a typical Rayleigh fractionation model. As garnet nucleates and grows at high
772 temperature (T>750°C), the matrix is progressively depleted in HREEs on a large scale due to the
773 presence of melt along grain boundaries that favor fast element mobility and rock-wide
774 equilibration. Simultaneously, the matrix is passively enriched in LREE on a rock-wide scale due
775 to the low garnet/matrix partition coefficients for LREEs (Moore et al., 2013). The rapid
776 intergranular mobility for all REEs with respect to garnet growth, without any dependence on
777 atomic number, precludes the establishment of diffusion gradients in the matrix, resulting in
778 smooth core-to-rim zoning and a transition from bell-shaped HREE to bowl-shaped LREE profiles.

779 Small garnets located in the quartz-saturated host granulite (e.g. Garnet G) are
780 characterized by a significantly HREE-depleted composition compared to large garnets located in
781 the quartz-undersaturated selvage adjacent to the leucosome (Garnets A and B), whereas their
782 LREE content remains similar. This discrepancy in REE concentrations could be related to a later
783 nucleation of garnets located in the quartz-present host granulite. Assuming a rapid
784 intergranular mobility and rock-wide equilibration for REEs, the early nucleation and enhanced
785 growth of garnet in proximity to the leucosome may have induced a bulk-rock HREE depletion at

the scale of the distance between Garnet A and Garnet G (~7 cm). In contrast, the small garnet/matrix LREE partitioning coefficient has a negligible effect on the bulk rock composition, resulting in an approximately constant LREE concentration for garnet regardless its nucleation and growth history.

Post-growth intragranular diffusion of major and trace elements

Calcium maps and profiles from Garnets B-G reveal that their prograde growth zoning is modified bear the inner core inclusions. This post-growth modification resulted in chemical re-equilibration of the grossular content to varying degrees, depending on the location of the garnet with respect to the quartz-undersaturated selvage and the host granulite. In the quartz-saturated host granulite, the smallest garnets (which also contain the biggest polyphase inclusions) show a complete (Garnet F) or partial re-equilibration (Garnets C, D, E, G) of the garnet core in contact with the inclusions, with grossular content decreasing to 3%, corresponding to the rim composition. This suggests that post-growth modification occurred near peak P-T conditions (0.8 GPa; 790°C). Located in the quartz-undersaturated selvage, the largest analyzed grain (Garnet B) also shows post-growth modification of bell-shaped Ca zoning, but chemical re-equilibration at peak-metamorphic conditions was only partial, with a minimum grossular content of 8% in the garnet core.

The modification of garnet cores in contact with polyphase inclusions and their strong similarity with matrix compositions requires a pervasive connectivity to permit such rock-wide re-equilibration to proceed. Both X-ray tomography (Figure 7) and LA-ICP-MS mapping (e.g. linear features highlighted in Li map; Figure 10) reveal the presence of a network of open channels and re-healed cracks that may have acted as potential connecting pathways. These features confirm that the garnet core was not isolated or armored from the matrix, but was rather freely accessible to the extent that fluid access along these discrete open fractures or larger conduits (Figure 7) may favor cation transport and garnet re-equilibration.

Furthermore, we suggest that REEs are also susceptible to the post-growth re-equilibration process. In contact with the polyphase inclusions in Garnet B, the bell-shaped HREE profile is modified with a decrease in Ho, Dy and Tb that correlates with the Ca zoning (Figure 12). The remaining HREEs are apparently unaffected by this modification, whereas the modification of LREEs such as Sm, Gd, La and Ce is more challenging to interpret. This is largely because the bowl-shaped profile for Sm and Gd, as described above, could also be enhanced by a depletion in LREEs next to the inner core inclusions. However, Grain G does show a pronounced depletion in LREEs at the garnet core, resulting in zoning that closely mimics the Ca distribution (compare Figs 9g and 13). Unlike Grain B, the absence of significant depletion in Ho, Dy and Tb, coupled with its lower HREE content and well-preserved bell-shaped HREE profile, may support the interpretation that Grain G represents a late nucleating garnet in the host granulite at peak metamorphic condition. Post-growth modification proceeded at a lower temperature where only LREE remained mobile, in the presence of F, Cl and/or P complexes (Ague, 2017; Migdisov, Williams-Jones & Wagner, 2009; Williams-Jones, Migdisov & Samson, 2012). Alternatively, it may suggest that selective REE mobility is coupled to Ca substitution via retrograde garnet-plagioclase exchange that favors LREE over HREE according to kinetic controls and element compatibility.

Role of changes in accessory phases and major rock-forming minerals

In the studied sample, the LREE + P whole rock budget is largely controlled by the stability of monazite. As such, an approximately constant LREE concentration for garnet whatever its nucleation and growth history, coupled with a smooth bowl-shaped LREE + P profile prior to post-growth modification (i.e. Garnet A; Figure 13), suggests that monazite did not grow on the prograde path. Bulk rock fractionation of this kind is incompatible with garnet-monazite partitioning relationships if their growth was coeval (Warren et al., 2019). Rather, the apparent lack of monazite competition for LREE + P throughout the garnet growth history necessitates that monazite first appeared at peak conditions, consistent with the U-Pb age interpretation

839 documented previously and further explained below.

840 Superimposed on the bowl-shaped LREE profile, the rims of Garnets B and G show a
841 sharp coincident enrichment in Ce, La and P where garnet is in contact with the matrix
842 assemblage consisting of plagioclase and biotite. The same sharp enrichment is observed next to
843 polyphase plagioclase and quartz inclusions located in garnet cores. There are two possibilities
844 for explaining LREE enrichment. We suggest that these sharp enrichments may reflect
845 modification of garnet zoning during post-peak breakdown of monazite. This interpretation is
846 consistent with the pervasive occurrence of thin Y-rich overgrowths on monazite located in the
847 matrix (Figure 18c), which may represent dissolution-precipitation events during the retrograde
848 evolution. Plagioclase breakdown may also contribute to the LREE enrichment since garnet rims
849 are locally enriched in large ion lithophile elements (LILEs) such as Ba and Sr, further suggesting
850 that post-peak garnet-plagioclase exchange is responsible for the modified grossular zoning and
851 that monazite ages reflect the timing of partial melting prior to breakdown on the retrograde
852 path.

853 The outermost rims of garnets are characterized by a sharp increase in Y and HREEs along
854 grain boundaries (Figures 10-13). This local enrichment is interpreted to be the result of partial
855 garnet breakdown during decompression via reactions (2) and (3) and back-diffusion of elements
856 that strongly partition into garnet with respect to the matrix. Notably, the absence of sharp
857 HREE and Y enrichment in core domains, despite an apparently pervasive matrix connectivity
858 during post-growth re-equilibration and simultaneous monazite replacement, confirms that
859 garnet resorption must have post-dated these events.

860 Similar to the HREEs, Zr zoning is radial in all garnets except for sharp spikes adjacent to
861 grain boundaries (figure S4). There are no satellite peaks or annular maxima indicative of zircon
862 breakdown, nor are there any pronounced depletions indicative of sudden zircon crystallization.
863 This suggests that zircon grew on the prograde P-T path, with the bulk rock Zr budget
864 progressively depleted as zircon and garnet grew under rock-wide equilibrium. The distribution
865 of U-Pb dates supports this interpretation, with concordant zircon analyses at 2.07 Ga being

similar to the 2.06 Ga monazite age inferred to represent peak metamorphism and partial melting. Rimward spikes in Zr are coincident with the HREE and Y enrichment noted above and slope away from the grain boundary, thus most likely due to garnet resorption rather than zircon breakdown.

CONCLUSIONS

The petrological and geochemical investigations of this partially melted granulite highlight the complexity of processes involved during partial melting at a scale ranging from a few microns to centimeters. This study confirms and shows that partially melted rocks are open systems in which changes in P-T conditions, deformation and mass transfer, that we have defined as melt-driven metasomatism, are preserved in the mineralogical assemblage and the major and trace element distribution revealed by X-ray microprobe and LA-ICPMS mapping respectively. One of the main challenges is to be able to distinguish the mineralogical records of a process like metasomatism from those related to changes in P-T conditions.

A first key observation and interpretation is that melt segregation and extraction coupled with changes in P-T conditions (due to decompression in this example) induce local disequilibrium between the segregated melt and the residual host-rock. The establishment of chemical potential gradients at the interface of these two sub-systems drives diffusive mass transfer. Our thermodynamic modeling shows that while H_2O, Na_2O, CaO and K_2O are transferred from the melt to the host rock, SiO_2 diffuses in the opposite direction. This combined mass transfer results in the formation of a quartz-rich and almost anhydrous leucosome and a quartz-undersaturated selvage at the expense of the host-granulite. Depending on the initial bulk-rock composition, P-T conditions of melt extraction and shape of the P-T path, the element that will diffusive (or not) in or out the melt domain and the residue will vary. We suggest that the variety of mineralogical compositions encountered in selvages surrounding leucosomes in migmatites

892 relates directly to these environmental variables and the induced melt-driven metasomatism.

893 Garnets show a complex major and trace element distribution that varies consistently with the
894 petrographic setting. We suggest that preserved chemical zoning reflects the superposition of
895 changes in P-T conditions and melt-driven metasomatism. Major and trace element zoning was
896 first acquired during prograde and peak metamorphism garnet growth in a temperature range of
897 675 and 790°C. Garnet grew mostly as a peritectic phase during biotite-dehydration melting
898 reaction. Calcium, Y and HREEs (from Lu to Dy), are characterized by a bell-shape distribution
899 and LREEs (from La to Gd) show a bowl-shape. The chemical zoning is consistent with a typical
900 Rayleigh fractionation model with fast intergranular element mobility of all elements, including
901 REEs, and rock-wide equilibration. The fast mobility is enhanced by the presence of melt along
902 grain boundaries.

903 The post-peak melt-driven metasomatism event is responsible for the modification of the
904 prograde zoning growth. Both Calcium and REE's are susceptible to the post-growth alteration
905 and results in a complete or partial re-equilibration through diffusion of garnet composition at
906 the P-T-X conditions of metasomatism (0.8 to 0.5 GPa; 790°C). Garnet cores in contact with
907 polyphased inclusions were affected by the post-growth modification due to the presence of a
908 network of open channels and cracks that act as connecting pathways between the matrix and
909 garnet core. Once again, at these high temperature conditions and in the presence of melt (and
910 fluid), divalent cation (Ca^{2+}) and REE are characterized by fast inter-granular and intragranular
911 element mobility and rock-wide equilibration. We conclude that in this peculiar case (high
912 temperature and melt/fluid-bearing open system), REE are not less vulnerable to diffusive
913 resetting than divalent cations.

914 Besides the interpretations regarding the formation of the quartz-undersaturated selvage and
915 the mobility of major and trace elements at high temperature conditions, this contribution
916 shows that an inaccurate interpretation of chemical zoning in garnet could result in misleading
917 thermobarometric results. Indeed, if the modified garnet core compositions (i.e. low calcium
918 content) were used as the chemical fingerprint of the early garnet nucleation stage it would

have resulted in erroneous low-pressure condition estimates for garnet nucleation.

ACKNOWLEDGEMENTS

This work was partially supported by the program CAPES-COFECUB n°624/09. We greatly acknowledge Johildo Barabosa and Hervé Martin, the main investigators of the program. We thank Johildo Barbosa for introducing the Farol da Barra outcrop and for the fruitful discussions. The structural analysis is part of the PhD dissertation of JSS funded by the program CAPES-COFECUB n°624/09. Jean-Luc Devidal is acknowledge for the assistance during EMP analysis at the Laboratoire Magmags et Volcans, Université Clermont-Auvergne and David Floess for the X-ray microtomography at the Institute of Earth Sciences, Univeristy of Lausanne. PG is very grateful to Marylène Monnot and Hugo Bourque that contributed to the petrological study of this sample while they were undergraduate students at the University of Franche-Comté. We would like to acknowledge Gregory Dumond and an anonymous reviewer for their constructive and helpful comments that helped improve this manuscript. Bernardo Cesare is acknowledge for his useful suggestions and the editorial handling.

940

941

942 Figure 1. (a) Aerial photograph of the Farol da Barra outcrop in the city of Salvador da Bahia,
943 with a corresponding structural and geological map (right-hand side). (b) Simplified structural
944 cross section including the studied area, showing the finite strain pattern consisting of a gently
945 dipping S1 fabric and steeply dipping D2 high strain zones. On both figures, the location of the
946 studied sample 06SB06 is shown as a red star.

947

948 Figure 2. (a) Photograph of the studied outcrop showing the steeply dipping S2 gneissic foliation.
949 The leucosome is surrounded by a melanocratic quartz-undersaturated selvage. (b) Polished slice

950 of the studied sample 06SB06 showing the location of the three thin sections.

951

952 Figure 3. (a) Photomicrograph of the metamorphic assemblage in the quartz-saturated granulite.
953 (b) Cordierite development at the contact between garnet and sillimanite in the quartz-
954 saturated granulite. (c) Spinel and cordierite symplectite developed at the expense of garnet
955 and sillimanite in the quartz-undersaturated selvage.

956

957 Figure 4. Thin-section scans under crossed-polarized light showing the location of the seven
958 analyzed garnets (A to G). Garnets A and B are located in the quartz-undersaturated selvage.
959 Notice the change in grain size and proportion of inclusions with increasing distance from the
960 leucosome.

961

962 Figure 5. Photomicrographs of the seven analyzed garnets. (a) Garnet A; (b) Garnet B; (c) Garnet
963 C; (d) Garnet D; (e) Garnet E; (f) Garnet F; (g) Garnet G. The size of the scale bar shown is 50
964 μm for all cases, and dashed lines correspond to the location of major element profiles shown in
965 Figure 9.

966

967 Figure 6. Backscattered electron images of crystallized melt inclusions in the outer rim of Garnet
968 B located in the quartz-undersaturated selvage. (a), garnet negative crystal shape crystallized
969 melt inclusion; (b) polyphase xenomorph crystallized melt inclusion; and (c) radial crack
970 attesting to melt inclusion decrepitation

971

972 Figure 7. (a) Backscattered electron image of a representative garnet in the quartz-saturated
973 granulite. (b) 3D reconstruction from a computed X-ray microtomography of garnet. (c-f)
974 sequential slices of the 3D reconstructed garnet (in red) showing the channels (white arrows)

975 connecting the irregular inclusions (transparent) to the outside matrix.

976

977 Figure 8. (a) Cathodoluminescence images of K-feldspar texture (blue) with plagioclase films and
978 pool (brown) along grain boundaries. Plagioclase films are connected to myrmekite pools (m).
979 (b) Extensive replacement of K-feldspar by plagioclase and myrmekites.

980

981 Figure 9. Garnet composition (black square = molar amount of grossular and white square =
982 XMg). The location of each line profile is shown in figure 5. The dark and light gray stripes
983 correspond to plagioclase-quartz inclusions and domains with minute inclusions of quartz,
984 respectively.

985

986 Figure 10. LA-ICP-MS trace element maps of (a) garnet A; (b) Garnet B; (c) Garnet G.
987 Concentrations values are in ppm. The line profiles shown in Figure 11-13 are located in each
988 case on the Phosphorus (P) map.

989

Figure 17

Figure 17. P-T phase diagram section computed with a modeled quartz-undersaturated selvage composition produced after a 47% loss of SiO2 and 140% gain of H2O. See Table 1 for compositions.

179x103mm (300 x 300 DPI)

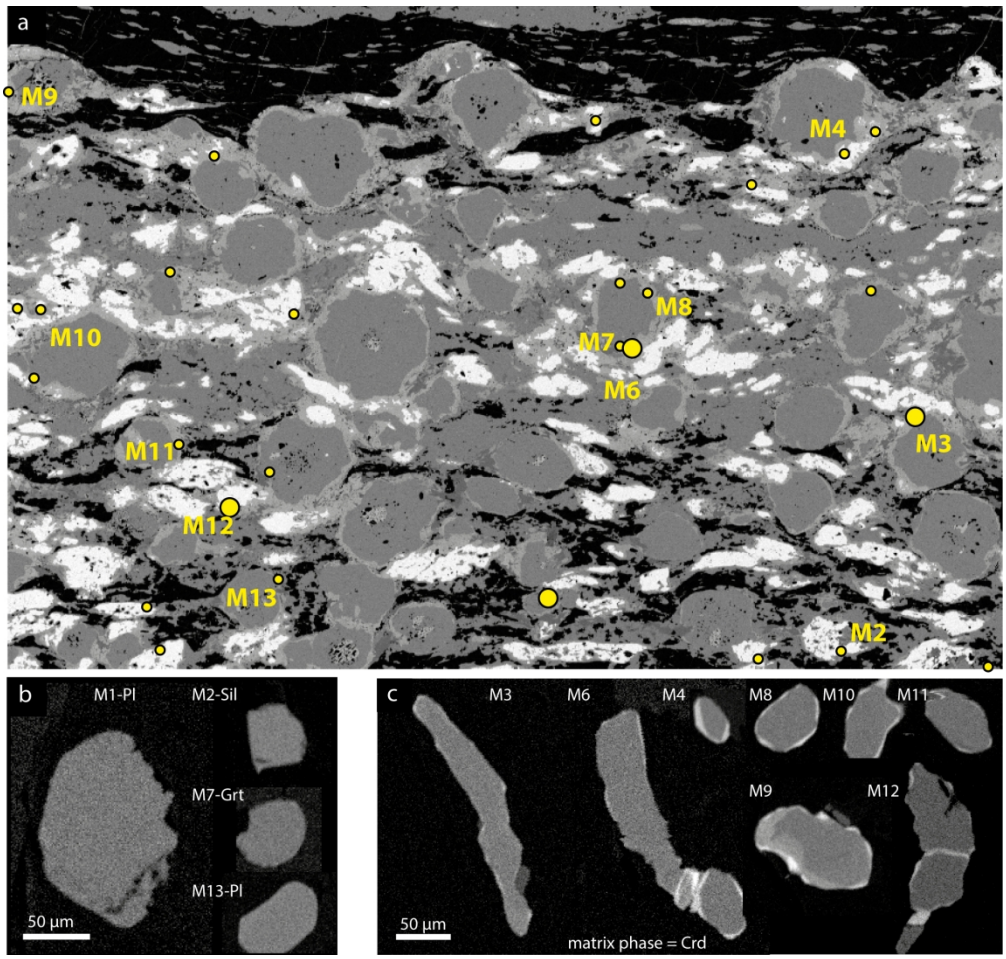

Figure 18. (a) Full thin-section X-ray Al map of sample 06SB06a showing the petrographic setting of dated monazites. (b) Y map of monazite included in garnet and plagioclase. (c) Y map of monazite in the cordierite-bearing matrix. Note the presence of thin Y-rich overgrowths.

180x171mm (300 x 300 DPI)

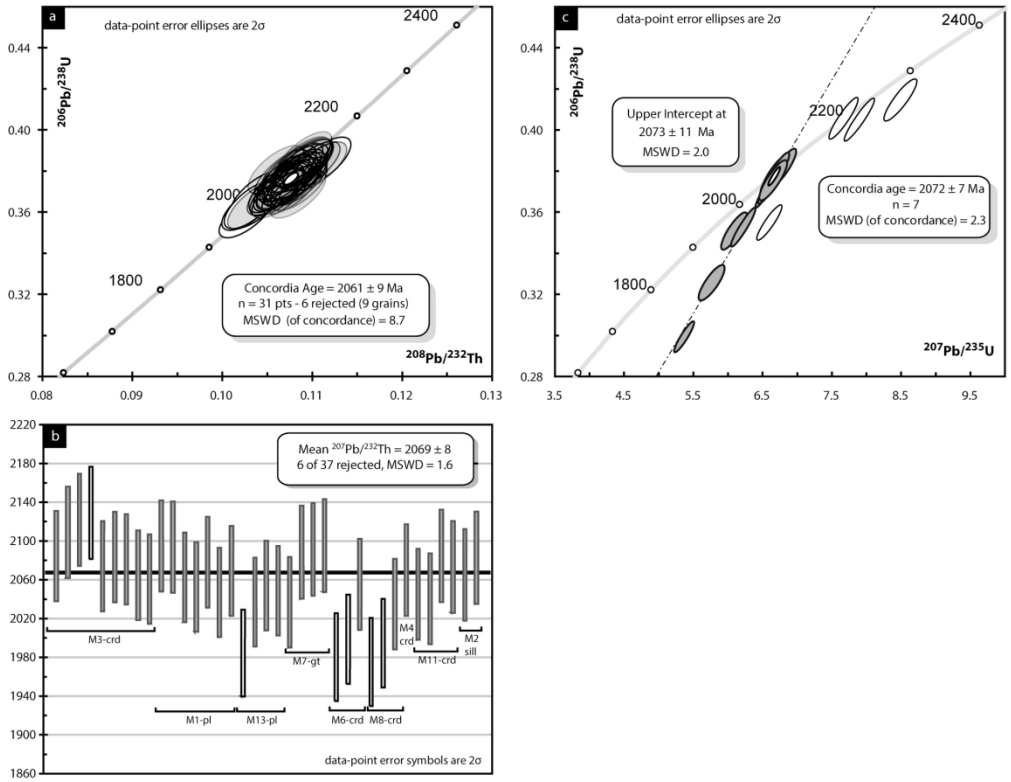

Figure 19. (a) Monazite U-Th-Pb concordia diagram. (b) Monazite Th-Pb ages. (c) Zircon U-Pb concordia diagram

180x139mm (300 x 300 DPI)

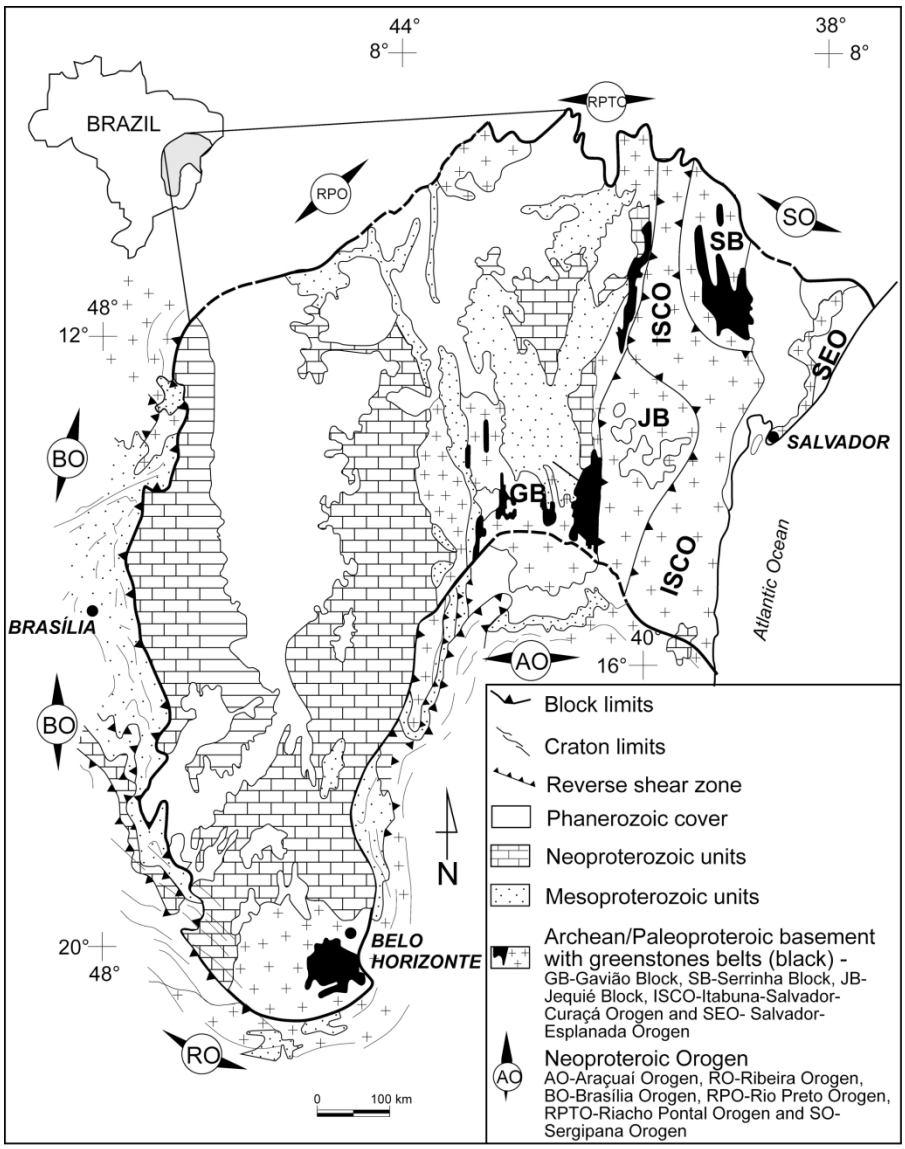

Figure 1

Figure S1. Simplified geological map of the São Francisco Craton modified after Barbosa et al. (2003).

180x240mm (300 x 300 DPI)

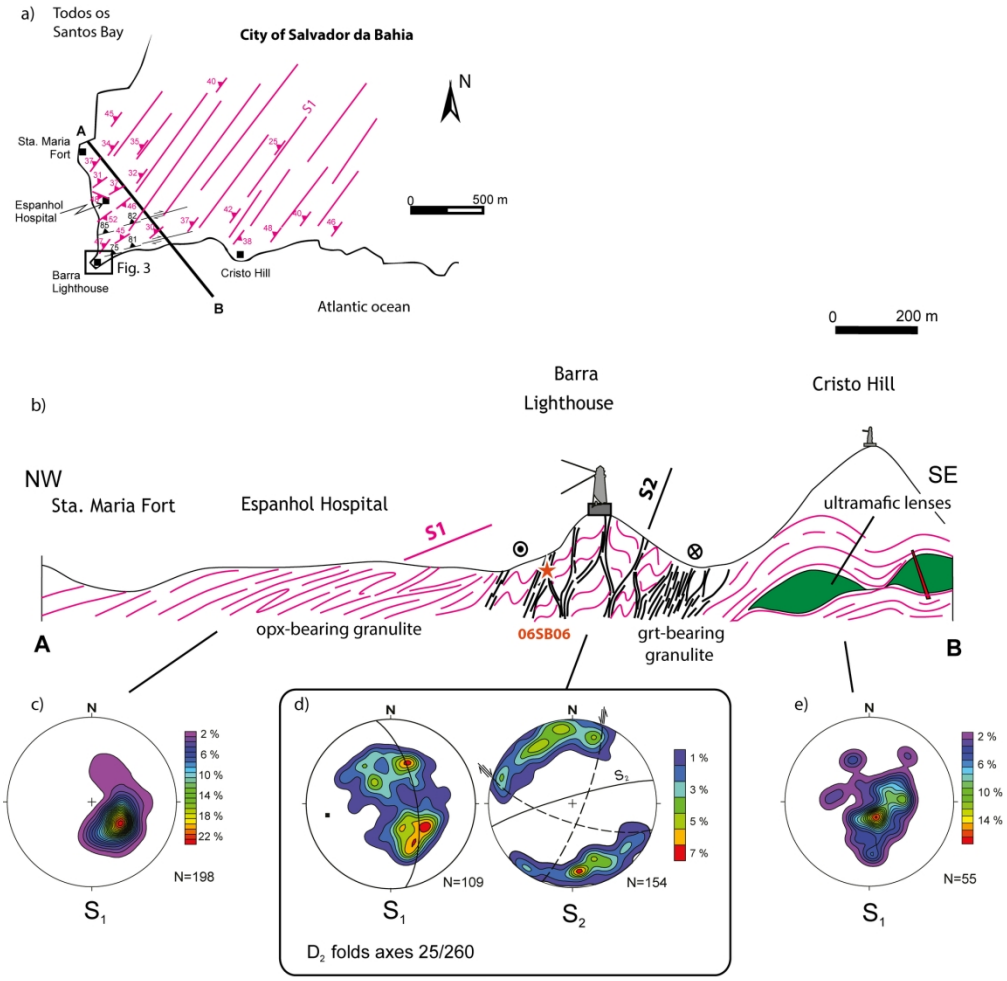

Figure S1

Figure S2. (a) Simplified structural map of the southwestern part of the city of Salvador da Bahia. (b) Simplified structural cross-section. (c) Equal-area Schmidt lower hemisphere projection of poles to S1 and S2 foliations (dashed lines = conjugated shear zones associated the S2 mylonitic foliation).

180x197mm (300 x 300 DPI)

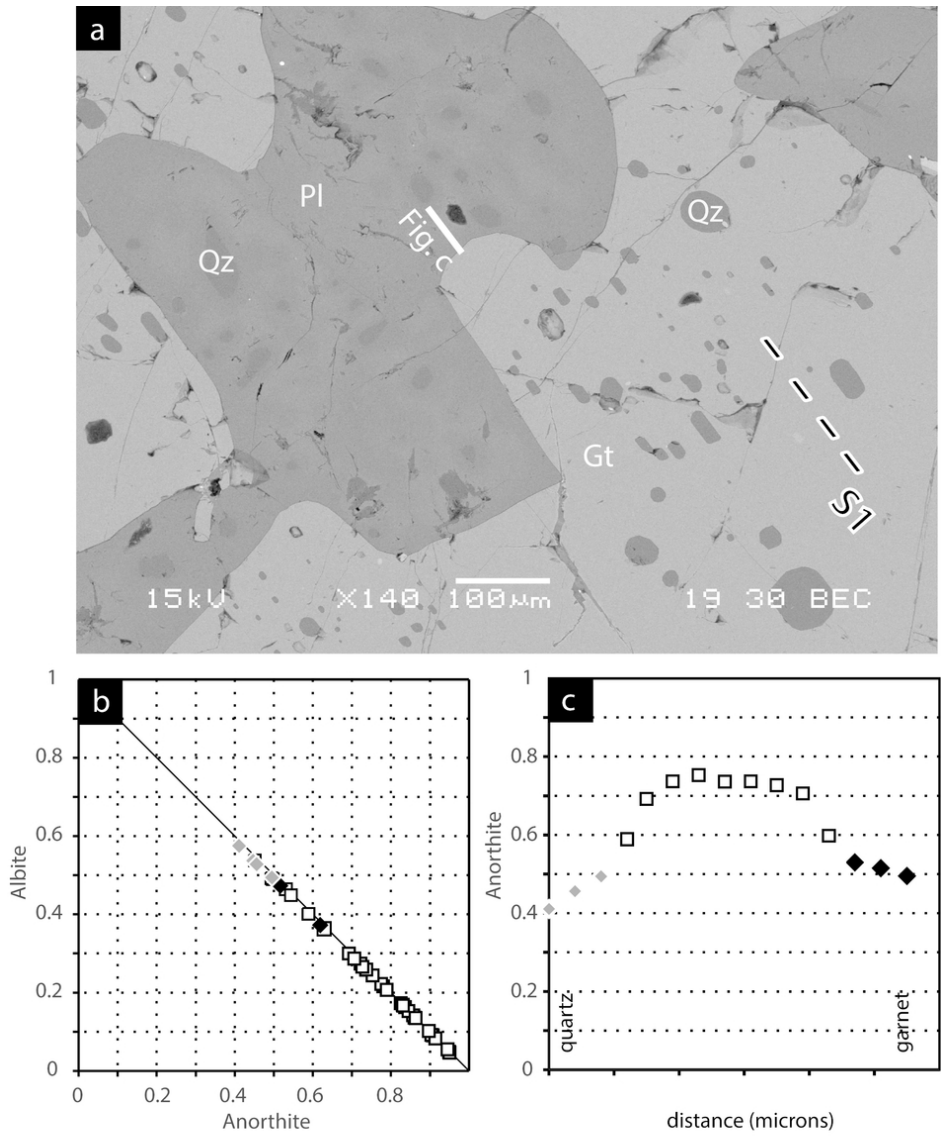

Figure S3

Figure S3. (a) Backscattered image of a polyphased plagioclase and quartz inclusion in a garnet. (b) anorthite vs albite content in mole of plagioclase. Grey and black diamonds are plagioclase composition in contact with quartz and garnet respectively. (c) Profile showing the evolution of plagioclase composition in contact with quartz and garnet. See location of the profile in figure a.

80x102mm (300 x 300 DPI)

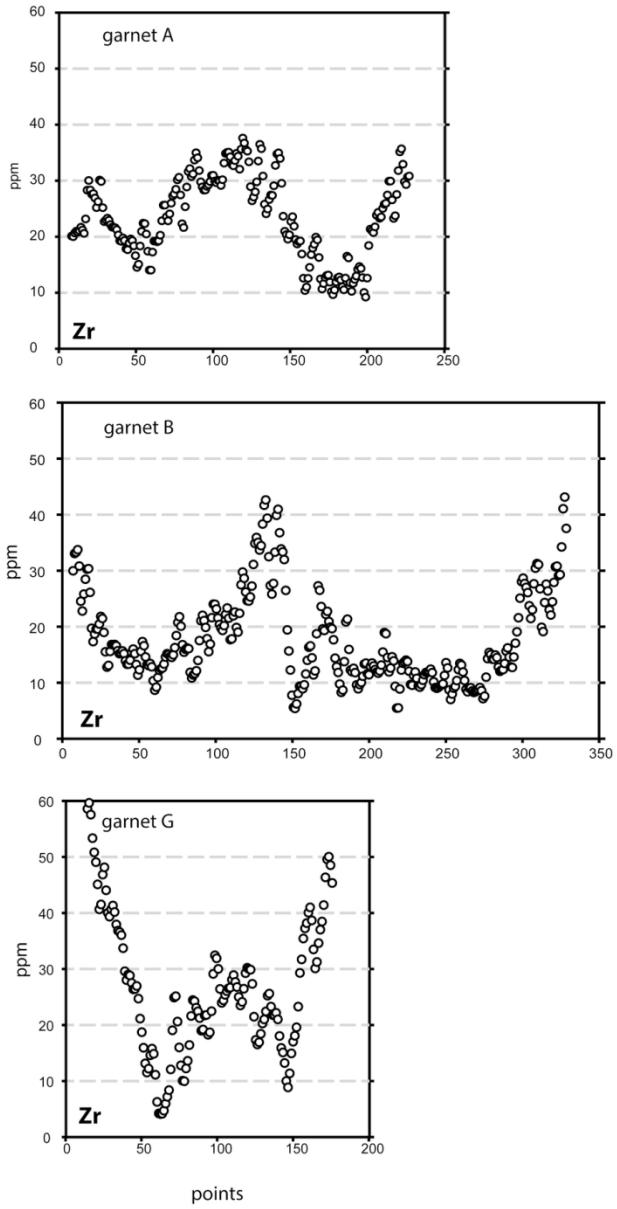

Figure S4. LA-ICP-MS Zr line profile of garnet A, B and G

80x156mm (300 x 300 DPI)

APPENDIX S1 : Trace element LA-ICP-MS analytical procedure

LA-ICP-MS trace element maps were acquired using a Resonetics M-50-LR 193 nm excimer laser coupled to an Agilent 7700x Quadrupole ICP-MS housed at Adelaide Microscopy, University of Adelaide. Instrument conditions and mapping protocols similar to that employed in this study are outlined by (Raimondo et al., 2017). Mapping was performed on standard 30 μm-thick polished thin sections by ablating a series of parallel rasters across the sample surface to form a square or rectangular grid. A beam diameter of 16 μm coupled with a laser repetition rate of 10 Hz produced an energy density of ~3.5 J/cm^2 at the target, and a scan speed of 22 μm/s and line spacing of 16 μm were used.

Data acquisition was performed in time-resolved analysis mode as a single continuous experiment. Each analysis comprised a suite of 39 elements (Figures S4-S6 and Datasets S1 and S2); dwell times for major elements were 0.005 s (to reduce excessive count rates) and all other masses were 0.008 s, giving a total sweep time of 0.31 s. Standards were analysed in duplicate at the start and end of each mapping run, and included reference glasses NIST 610 and 612 (Jochum et al., 2011; Pearce et al., 1997) and garnet standard MON-GT (C. Harris & Vogeli, 2010; Chris Harris et al., 2000). Data reduction was performed using the software *Iolite* (Hellstrom et al., 2008; Paton et al., 2011; Woodhead et al., 2007), with quantification via the Trace Elements DRS applied using ^{29}Si for internal calibration, applicable to garnet pixels only. Finally, image and data processing was completed using *XMapTools* 2.3.4 (Lanari et al., 2014; Raimondo et al., 2017) and *ImageJ* (Abramoff, Magalhães & Ram, 2004).

Appendix S2 : U-Th-Pb monazite and zircon geochronology analytical procedures

The identification, distribution and characterization of chemical zoning of monazite was performed in-situ, following the approach of Williams, Jercinovic, Goncalves & Mahan (2006), on a Cameca SX100 ® electron microprobe at the Laboratoire Magmas et Volcans in Clermont-Ferrand (France). All monazite grains were identified through full-thin-section X-ray mapping for Ce Lα, P Kα along with Al Kα, Mg Kα to obtain a mineralogically and texturally map in order to reveal the monazite distribution with respect to the leucosome, quartz saturated and undersaturated domains (Figure 18). Analytical conditions were a 15 keV accelerating voltage with a 200 nA beam current, a defocussed beam at 35 µm, and a counting time of 9 ms per pixel with a 35 µm pixel setp size. High resolution compositional maps were performed on all the selected grains for Y Lα, Ca Kα, Th Mα and U Mß. Analytical conditions were 15 kV, 200 Na with a rastering focussed beam. Counting time varies from 100 to 150 ms, with a step size ranging from 0.4 to 1 µm. Intensities of all raw compositional were normalized in counts per second and processed all together so that gray levels (i.e. composition) and zoning features can be compared from grain to grain. Zircon were identified via a conventional optical microscope.

U-Th-Pb geochronology of zircon and monazite was conducted by laser ablation inductively coupled plasma spectrometry (LA-ICPMS) at the Laboratoire Magmas et Volcans, Clermont-Ferrand (France). The analyses involve the ablation of minerals with a Resonetics Resolution M-50 powered by an ultra short pulse ATL Atlex Excimer laser system operating at a wavelength of 193 nm (detailed description in Müller, Shelley, Miller & Broude (2009). Spot diameters of 20-26 µm and 7 µm associated to repetition rates of 3 Hz and 1 Hz were used for zircon and monazite respectively. The ablated material is carried into helium, and then mixed with nitrogen and argon, before injection into a plasma source of an Agilent 7500 cs ICP-MS equipped with a dual pumping system to enhance the sensitivity.

The alignment of the instrument and mass calibration was performed before every analytical session using the NIST SRM 612 reference glass, by inspecting the signal of 238U and by minimising the ThO+/Th+ ratio (<< 1%). The mean sensitivity on ^{238}U at the instrumental conditions reported in Table 1 and using a spot size of 44 µm is about 15-20,000 cps/ppm. The analytical method for isotope dating of monazite with laser ablation ICPMS is basically similar to that developed for zircon and monazite and reported in Paquette & Tiepolo (2007) and Tiepolo, Bottazzi, Palenzona & Vannucci (2003). The signal of ^{204}(Pb+Hg), ^{206}Pb, ^{207}Pb, ^{208}Pb, ^{232}Th and ^{238}U

masses are acquired. The occurrence of common Pb in the sample can be monitored by the evolution of the ^{204}(Pb+Hg) signal intensity, but no common Pb correction was applied owing to the large isobaric interference from Hg. The ^{235}U signal is calculated from ^{238}U on the basis of the ratio ^{238}U/^{235}U= 137.88. Single analyses consisted of 20 seconds of background integration with laser off followed by 1 minute integration with the laser firing and a 20 seconds delay to wash out the previous sample (approximatively 10 seconds for 6 orders of magnitude) and prepare the next analysis.

Data are corrected for U-Pb and Th-Pb fractionation occurring during laser sampling and for instrumental mass discrimination (mass bias) by standard bracketing with repeated measurements of GJ-1 zircon (Jackson, Pearson, Griffin & Belousova, 2004) or Moacyr monazite (Gasquet, Bertrand, Paquette, Lehmann & Ratzov, 2010) standard. Data reduction was carried out with the software package GLITTER® (Macquarie Research Ltd, 2001; Jackson et al. (2004); Van Achterbergh, Ryan, Jackson & Griffin (2001). For each analysis, the time resolved signal of single isotopes and isotope ratios was monitored and carefully inspected to verify the presence of perturbations related to inclusions, fractures, mixing of different age domains or common Pb. Calculated ratios were exported and Concordia ages and diagrams were generated using Isoplot/Ex v. 2.49 software package by Ludwig (2001). The concentrations in U-Th-Pb were calibrated relative to the certified contents of 91500 zircon standard (Wiedenbeck, Allé, Corfu, Griffin & Meier, 1995) and Moacyr monazite (Seydoux-Guillaume, Wirth, Deutsch & Schärer, 2004).
