ABSTRACT

Volcanic tephra fall deposits, which form during explosive eruptions, are commonly characterized in terms of their thickness and grainsize. While significant efforts have been undertaken to relate spatial trends in thickness to plume dispersion processes, comparably few studies have focused on understanding variations in grainsize. Yet, grainsize is a key parameter providing insight into eruption dynamics, from magma fragmentation to plume transport processes, and modulates the impacts of tephra. Here, we present a set of grainsize data extracted from the published record for 56 deposits that represent a range of eruption intensities and magnitudes. We systematically analyze the deposits in terms of modality (bimodal or unimodal grainsize distributions) and provide the median particle diameter with distance from source for component distribution modes. We found that bimodal fall deposits are formed by eruptions with large amounts of fine particles (<100 µm) and that all tephra-fall deposits show characteristic patterns of grainsize decay with distance from source that can be related to eruption plume height and thus intensity. The grainsize decay trends are also related to ash dispersion and deposition processes such as individual particle settling versus collective settling mechanisms. The maximum distance from source reached by particles of different sizes is controlled by a combination of source and transport processes. This data set provides insight into the preservation potential of deposits of different grain sizes at varying distances from their sources. Finally, we emphasize the importance of using grainsize trends in combination with thickness trends to interpret tephra-fall deposit records.

INTRODUCTION

Explosive volcanic eruptions inject great amounts of particles, called tephra, into the atmosphere, which can be transported long distances before they are deposited on the ground, where they create widely dispersed, continuous layers blanketing topography. These tephra-fall deposits generally decrease in thickness and grainsize away from source (Thorarinnsson, 1954; Pyle, 1989; Bonadonna et al., 2015c), which enables eruption size to be inferred (i.e., volume, magnitude, and intensity; Pyle, 1989, 1995, 2000; Bonadonna et al., 2015a) and the study of eruption processes (i.e., eruption column dynamics, plume height, explosivity, style; Walker, 1971; Walker, 1973; Carey and Sparks, 1986; Burden et al., 2011; Rossi et al., 2019). In particular, the grainsize of tephra-fall deposits provides information about magma ascent and fragmentation processes (e.g., Alidibirov and Dingwell, 1996; Rust and Cashman, 2011; Dellino et al., 2012; Liu et al., 2015) and the mechanisms of volcanic plume formation, dispersion, and sedimentation through the atmosphere (e.g., Carey and Sigurdsson, 1982; Costa et al., 2010; Girault et al., 2014; Manzella et al., 2015; Del Bello et al., 2017).

The grainsize of fall deposits is generally measured at individual locations by combining mechanical clast sieving and fines-sensitive analytical methods, such as laser diffraction and dynamic image analysis (e.g., using CAMSIZER or MORPHOLOGIG3; Eychenne et al., 2012; Buckland et al., 2021). These individual measurements are often spatially interpolated to obtain the total grainsize distribution (TGSD) of the deposit (Bonadonna and Houghton, 2005; Bonadonna et al., 2015a; Costa et al., 2016; Pioli et al., 2019), which is an estimate of the total particle size distribution within the buoyant convective column before transport fractionation processes occurred. TGSDs are widely used as inputs in numerical models of tephra transport and deposition (Costa et al., 2006;

Osman et al., 2020) and to assess mechanisms of magma fragmentation (Rust and Cashman, 2011; Cashman and Scheu, 2015). Trends in maximum grainsize form the basis of a plume ascent model (Carey and Sparks, 1986) updated in Burden et al. (2011) and Rossi et al. (2019) that is still used today to assess the plume height at the vent during explosive eruptions. In addition, numerical models of tephra transport and deposition are overwhelmingly developed and validated using thickness (or mass load) spatial variations (Folch et al., 2010; Beckett et al., 2015; Tadini et al., 2020) with relatively few studies validating model outputs using grainsize (Bonadonna et al., 2002a). The spatial variations of individual grainsize distributions in tephra-fall deposits are underexploited in comparison to other measurements such as deposit thickness.

Characteristic grainsize decay can be observed in several individual fall deposits. For example, the fall deposits from the Campanian Ignimbrite and Minoan eruptions show a decrease in median grainsize away from source before reaching a plateau of constant grainsize at large distances from source (constant grainsize between 950 km and 2300 km from vent in the Campanian Ignimbrite deposit, and 300 km and 500 km in the Minoan deposit; Sparks and Huang, 1980; Engwell et al., 2014). Similar trends were observed in the deposit from the 18 May 1980 Mount St. Helens eruption (Eychenne et al., 2015), and an analysis of published grainsize information for a large number of fall deposits (Engwell and Eychenne, 2016) implies that this is the same for deposits from a wide range of eruption dynamics. In comparison, a recent analysis of several phreatomagmatic deposits shows little change in grainsize with distance from vent (Osman et al., 2020). How these characteristic spatial grainsize trends vary across different eruption types, and how they relate to the fragmentation mechanisms, eruption dynamics, and the transport and deposition processes, are open questions.

†julia.eychenne@uca.fr.

Answering these questions would bring valuable new insights into the physics of explosive eruptions (from magma ascent to ejection) and volcanic plumes (from the formation at the vent to the dispersion in the atmosphere). Terms such as “proximal,” “medial,” and “distal” are commonly used when describing distance from source of volcanic deposits. These terms identify regions close to, intermediate from, and far from vent, respectively, and correspond to different absolute distances for fall deposits from eruptions of different sizes. No objective criteria exist to define proximal, medial, and distal regions, but this gap could be filled by using grainsize trends with distance.

Additionally, documenting how tephra is transported and spatially distributed in different eruption scenarios is key information for mitigating the impacts from tephra fall, such as those on aviation or health. Indeed, aircraft engines are particularly susceptible to ingestion of fine particles (Vasseur et al., 2013; Kueppers et al., 2014), and therefore it is important to understand to what distances such grainsizes are transported. The respiratory hazard for humans during or after eruptions is caused by the poor air quality resulting from the suspension of volcanic particles (Carlsen et al., 2015). Human respiratory systems are particularly susceptible to particles of less than 10 μm , which cause acute health effects (Baxter et al., 1981; Horwell and Baxter, 2006; Baxter et al., 2014). Quantifying the probability of tephra of given sizes reaching given distances in the atmosphere and on the ground is thus critical for these applications.

Finally, a thorough description and classification of grainsize trends in tephra-fall deposits would provide an invaluable tool for refining numerical models of tephra transport and deposition. Indeed, the major challenge with current models relates to the difficulty in reproducing the processes of particle sedimentation in the Earth’s complex atmosphere (Watt et al., 2015; Poulidis et al., 2021). Spatial grainsize trends on the

ground could be a robust means to test and validate these models. While the decay of grainsize distributions away from vent has been described for many deposits (e.g., Fisher, 1964; Brazier et al., 1983; Sparks et al., 1983; Engwell et al., 2014; Engwell and Eycheenne, 2016) and has been related to eruptive plume height and used for eruption classification (Pyle, 1989; Bonadonna and Costa, 2013), these studies typically have focused on a single or small number of eruptions.

To fill these gaps in knowledge, we analyzed grainsize information at various distances from vent from several tephra-fall deposits and systematically compiled this information into a self-consistent data set that allows the comparison and classification of fall deposits from eruptions spanning a wide range of magnitudes and intensities. We present characteristic spatial grainsize trends and correlate them with eruption dynamics. Our findings enable description of the heterogeneity of tephra-fall deposits and their spatial variability for different eruption scenarios and provide novel insight into the physical controls on tephra-fall deposit grainsize, from fragmentation to transport processes. They also have important implications for ash transport in distal reaches and the use of tephra-fall deposit records.

DATA SET

This study uses grainsize data and source parameters from 56 tephra-fall deposits from a range of magmatic and phreatomagmatic eruptions (Fig. 1 and Table 1). Grainsize and eruption information was collected from the published record (mostly peer-reviewed publications and some published masters and doctoral theses) and open access volcanological databases (e.g., Global Volcanism Program [Smithsonian Institution, <https://volcano.si.edu/>], the International Association of Volcanology and Chemistry of the Earth’s Interior Commission on Tephra Hazard Modeling [<https://thm.iavceivolcano.org/>],

and the Independent Volcanic Eruption Source Parameter Archive [Aubry et al., 2021]). All references are provided in Table 1 and listed in the Supplemental Material.¹

Information was collected on the characteristics of each tephra-fall deposit (e.g., stratification, grainsize polymodality, and grainsize measurement method; Table S1 [see footnote 1]). All of the grainsize distributions (GSD) compiled in this study were either unimodal or bimodal. Bimodal distributions have two distinguishable peaks, i.e., two modes. Narrow peaks (often a single phi or half-phi interval, where $\phi = -\log_2$ (particle diameter in mm)) in the coarse lapilli range (>8 mm) are not considered to be modes, as these are found in samples close to vent and most likely were caused by ballistic clasts (see, for example, GSDs from the 13 February 2014 Kelud eruption in Maeno et al., 2019).

Information on each associated eruption was also collected from the published record (Table 1) and includes:

(1) *Eruption type*, categorizing eruptions as either *magmatic* or *phreatomagmatic*.

(2) *Magnitude of tephra-fall deposit*, estimated from the mass of the tephra-fall deposit using the relation: $M = \log_{10}[\text{erupted mass (kg)}] - 7$ (Pyle, 2000). The deposit mass was either calculated from the deposit volume using a measured or assumed deposit bulk density or directly assessed from isomass maps in the publications (see Table S1).

(3) *Maximum column height above vent*, typically defined by observations (e.g., webcams, radar, or satellite remote sensing) or by applying empirical methods to deposits such as the model from Carey and Sparks (1986). The method used for each example is given in Table S1, along with the associated references.

(4) *Occurrence of pyroclastic density currents* (PDC), based on observations made during the eruptions or observations of PDC deposits stratigraphically associated with an eruption.

For some eruption parameters, the values inferred in the literature varied among sources, in which case we used an average or a consensual value. In cases where it was not clear whether plume height related to height above vent or sea level, we followed a methodology similar to that defined by Deligne (2021), whereby, for example, plume heights from pilot reports or satellite imagery are assumed to represent height above sea level rather than height above vent.

¹Supplemental Material. Containing one pdf file with Supplemental Information (Figs. S1–S4 and list of references from Table 1) and 3 Excel spreadsheets (Tables S1–S3). Please visit <https://doi.org/10.1130/GSAB.S.21066313> to access the supplemental material, and contact editing@geosociety.org with any questions.

Figure 1. Maximum column height versus magnitude is plotted for all of the eruptive events compiled in our data set (Table 1) except for the Hverfjall 2500 B.P. and Reykjanes 1126 CE phreatomagmatic eruptions, for which the plume height is unknown. Phreatomagmatic and magmatic eruptions are in gray and black, respectively. See Table 1 for information on the eruptive events and associated deposits, magnitudes, and plume height values, as well as references.

TABLE 1. SUMMARY OF THE 56 TEPHRA FALL DEPOSITS STUDIED FOR GRAINSIZE

Eruption/deposit ID	Volcano	Country	Date/deposit name	Deposit category	Source of grainsize data	Eruption type	Magnitude	Max plume height above vent (km)
Hverfall phreato	Kratla	Iceland	2500 yr B.P. Hverfall fires (phreatomagmatic unit)	Unimodal	[1]	Phreatomagmatic	3.9 [1]	Unknown

Note: Source references (numbers in []) for the grainsize data, magnitude, and plume height information are listed in the supplemental material (see text footnote 1). *Unpublished raw grainsize data are from C. Bonadonna and B. Houghton.

METHODS

Compiling and Processing Grainsize Information

The grainsize data set (Table S2; see footnote 1) includes the distance from vent (Dist) of individual tephra samples and the median diameter (Md) for each unimodal GSD, or, for bimodal GSDs, the Md of each individual deconvolved subpopulation, as explained below. Md is expressed here in millimeters and was converted from the Mdphi values (Inman, 1952) found in the relevant publications or calculated herein after deconvolution. Md represents the grainsize separating the lowest 50% from the highest 50% of values, and it is inferred graphically from a cumulative density function without assuming any distribution shape. All of the tephra samples compiled here correspond to tephra-fall deposits, i.e., areas where tephra deposition was significant enough to create a deposit identifiable by eye.

Several tephra-fall deposits in our data set are characterized by bimodal GSDs (Fig. S1; see footnote 1). The Md of a bimodal GSD is a poor measure of its characteristics because it does not correlate with the grainsizes of maximum occurrence (represented by the GSD's modes; Fig. S1). The Mds of the two subpopulations extracted from the GSDs by deconvolution define distinct and delimited variation fields. These cannot be identified from the analyses of the GSD Md variations (Fig. S2; see footnote 1), which highlights the lack of resolution of this latter parameter. Hence, in our grainsize data set, unimodal GSDs are described by a single Md, while bimodal GSDs are deconvolved by fitting each observable peak with a subpopulation distribution that is then described by its own Md.

In the published record, grainsize information is presented in various ways. In some sources, raw GSDs are provided as volume or weight probability density functions. They are often presented on phi scales and more rarely on metric scales. In other cases, only distribution statistics (e.g., mode, median, and sorting) are presented, commonly plot against sample location distance from vent. In the case of layered tephra-fall deposits, grainsize data refer in some sources to the complete deposit and in others to individual layers. To build a homogeneous data set and enable direct comparison of eruptions and deposits, we only include GSDs that reflect the whole deposit, including those showing stratification. Stratified deposits are identified in Table S1. While a deposit may exhibit individual units in proximal regions, it is often impossible to distinguish different units in distal

deposits, which likely represent either the most intense phase of the eruption or a contribution from multiple eruption phases, including both Plinian and co-PDC contributions. We used published Md values or calculated Md values from available GSDs. Published Md values were only used if evidence for the unimodality of the GSD was provided or if they referred to deconvolved subpopulations of bimodal GSDs. It is important to note that due to the criteria used, some of the grainsize information existing in the published record were not included in our data set.

The grainsize data compiled here were acquired by combining sieving in the coarse range (roughly coarser than 100 μm , but this varies among studies) and a variety of different measurement methods in the fine range. The grainsize analytical methods for each of the 56 eruptions in our data set are indicated in Table S2. These methods include (1) laser diffraction, based on the principle of light scattering (using instruments such as the Malvern Mastersizer or Beckmann Coulter); (2) sedimentation, based on the assessment of the particle size from the settling velocity using Stokes' law (pipette method, Sedigraph instrument); (3) electrosensing zone, based on the resistive pulse sensing in an electrical field (using instruments such as the Elzone Celloscope); and (4) dynamic image analyses, based on image acquisition and analyses of the particles dispersed in a flowing fluid (using instruments such as the Camsizer). Different measurement techniques can produce various grainsize distributions for a given sample (Buckland et al., 2021), which could explain some of the differences in grainsize among the tephra-fall deposits compiled here.

Deconvolution of Bimodal Grainsize Distributions

Raw bimodal GSDs were deconvolved using the fully automated DECOLOG software (Bellotti et al., 2010; Caballero et al., 2014), which uses an iterative algorithm for nonlinear fitting of log normal or Weibull functions. Following the approach described in Eychenne et al. (2015), only peaks with an overlap smaller than $\sim 70\%$ were deconvolved into individual subpopulations to avoid inaccurate deconvolution results. The deconvolution methods used in the publications from which we extracted pre-deconvolved Md values included (Table S2) software-based DECOLOG, SFT (Wohletz et al., 1989), and LOGN2D (Eychenne et al., 2012), as well as hand-fitting (Brazier et al., 1983). We hereafter refer to the two subpopulations extracted from the bimodal distributions as "coarse" and "fine."

RESULT OF THE GRAINSIZE ANALYSIS

Characteristics of the Eruptions in the Data Set

The 56 tephra-fall deposits in our data set (Table 1) were generated by magmatic and phreatomagmatic eruptions with a wide range of plume heights and magnitudes (Fig. 1). The plume height is a measure of the intensity of an eruption, i.e., the rate at which material is erupted (Pyle, 2000; Mastin et al., 2009). The magnitude refers to the total amount of material erupted (Pyle, 2000), and hence represents a measure of eruption size. There is a positive correlation between the amount of material erupted during an explosive eruption and the rate at which it is erupted (Carey and Sigurdsson, 1989; Pyle, 2000), as illustrated by the correlation between plume height and magnitude in our data set (Fig. 1). The deposit data set compiled here spans a representative range of magmatic eruptions, from low to high intensities and magnitudes. Only six eruptions in the data set are phreatomagmatic, but they span a comprehensive range of eruption intensities and magnitudes.

Different numbers of grainsize distributions from individual locations are available for each eruption. The number of data points, and the minimum and maximum distances from source at which these data points were collected for each eruption, are reported in Table S1. In general, eruptions with lower plume heights have more grainsize information closer to source, while for the largest eruptions, more data are available at large distances from vent.

Categories of Tephra-Fall Deposits

The 56 tephra-fall deposits analyzed here (Table 1 and Fig. S3; see footnote 1) can be grouped into distinctive categories based on their grainsize characteristics. Some deposits, hereafter referred to as *unimodal deposits*, are characterized by unimodal GSDs across the deposit extent (Fig. 2A) or are dominated by unimodal GSDs with rare bimodal GSDs at scattered locations (Fig. 2B). The boundary between unimodal deposits with and without scattered bimodal GSDs is indistinct; some deposits classified as unimodal here include subordinate bimodal samples that were disregarded due to the lack of raw data for deconvolution (e.g., the 1104, 1300, 1693, and 1766 Hekla eruptions; Janebo et al., 2018). Other deposits, hereafter referred to as *bimodal deposits*, are characterized by bimodal grainsize distributions throughout (Fig. 2C) or are dominated by bimodal GSDs but also show unimodal GSDs at distal locations (Fig. 2D).

Figure 2. Variations in median diameter (Md) of the grainsize distributions (GSDs) are plotted with the distance from vent for the four categories of tephra-fall deposits identifiable in our data set (Table 1): (A) unimodal, (B) unimodal with scattered bimodal distributions, (C) bimodal, (D) bimodal with distal unimodal distributions, and (E) all deposits. Symbols are used to distinguish Md values from unimodal GSDs (open circles), coarse subpopulations (filled circles), fine subpopulations (crosses), as well as distal unimodal GSDs (triangles). The data points are colored according to the maximum plume height above vent (column height) using a continuous color scale.

Both types of bimodal deposits show converging grainsize subpopulations with distance from vent that eventually merge in distal reaches and contribute to the distal unimodal GSDs (Fig. S1). The two categories of bimodal deposits probably represent a single category, assuming that bimodal deposits without unimodal GSDs at distal locations were not sampled at distances great enough to identify where the GSDs become unimodal.

Unimodal deposits are formed by a wide range of eruptions with low to high plume heights (<1–37 km; Fig. 2A). They also span a wide range of eruption magnitudes (0–5.9; Table 1). Unimodal deposits with scattered bimodal distributions were found for low to intermediate plume heights (5–18 km above vent; Fig. 2B) and magnitudes (~2–4; Table 1). Bimodal deposits were found for intermediate to high plume heights (11–30 km above vent; Fig. 2C) and magnitudes (1.7–5.9; Table 1). Bimodal deposits with distal unimodal distributions were found for high plume heights (>27 km above vent; Fig. 2D) and magnitudes (>4.7; Table 1).

Downwind Grainsize Variations

When examining the spatial variations of the grainsize data in a log–log space where Md and distance are both expressed in metric units, we identified three distinctive grainsize trends across all of the deposit categories (Figs. 2 and 3). A *coarse trend*, showing a clear decrease in Md with distance from vent, is defined by the unimodal GSDs and the coarse subpopulations of the bimodal GSDs (open and filled circles in Figs. 2 and 3). A *fine trend*, showing little change in Md with distance from vent, is defined by the fine subpopulations of bimodal GSDs (crosses in Figs. 2 and 3). Finally, a *unimodal distal trend* was defined that often follows the same

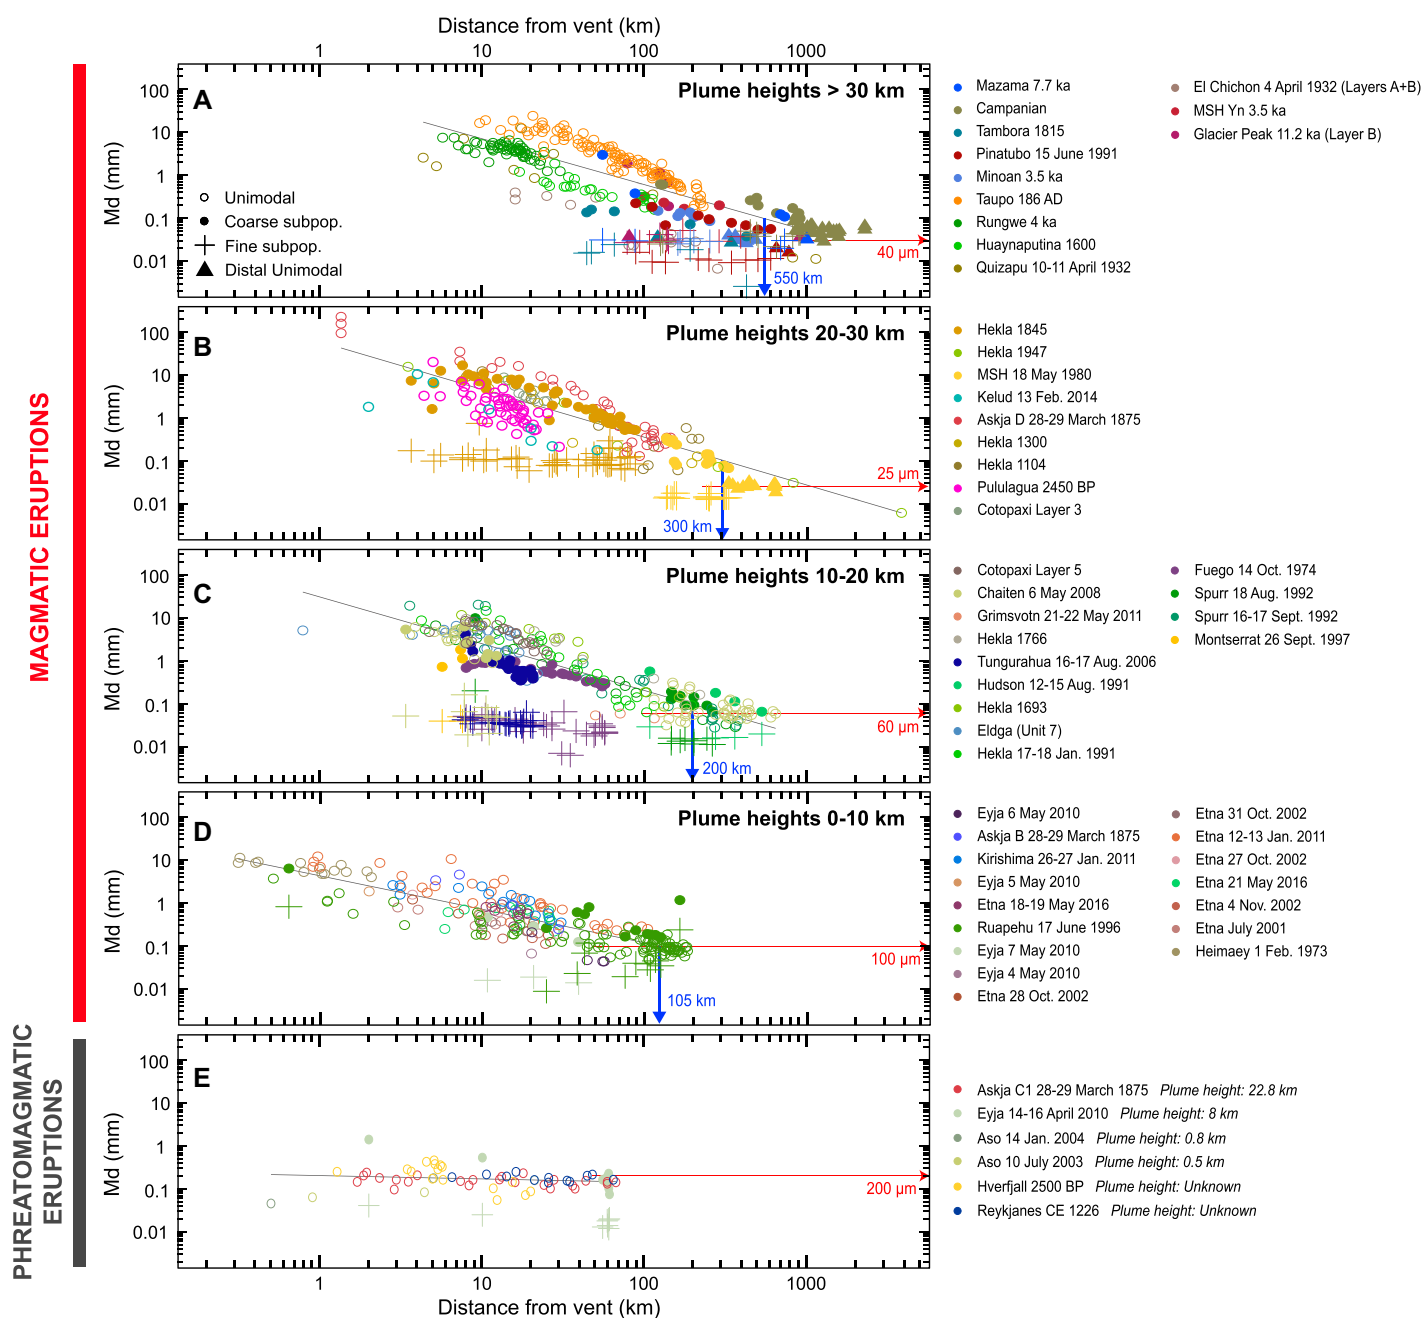

Figure 3. Variations in median diameter (Md) of the grainsize distributions (GSDs) are plotted with distance from vent for the (A–D) magmatic and (E) phreatomagmatic eruption deposits compiled in our data set. Magmatic eruptions are plotted separately based on the maximum plume heights above vent: eruptions with plume heights above vent (A) >30 km, (B) between 20 km and 30 km, (C) between 10 km and 20 km, and (D) between 0 km and 10 km. The data points are colored by deposit/eruptive event (see Table 1 for more information on the eruptions and references for the plume heights reported here) and ordered in the legend by decreasing plume heights. Symbols are used to distinguish Md values from unimodal GSDs (open circles), coarse subpopulations (filled circles), fine subpopulations (crosses), as well as distal unimodal GSDs (triangles). The gray lines represent the best fit through the coarse trend of deposits grouped by plume heights and magmatic versus phreatomagmatic eruptions. The blue arrows represent the distance from vent at which the best fit lines reach 100 μm . The red arrows highlight the grainsize at which the coarse and distal trends reach a plateau in Md distally.

trend as the fine trend where present, and that is restricted to large distances from vent, and shows little change in Md with distance (triangles in Figs. 2 and 3). Within each individual deposit

(Fig. 3), a range in Md is observed at constant distances from vent, which represents the cross-wind changes in grainsize. Despite this scatter, the coarse, fine, and distal unimodal trends have

distinctive characteristics that can be interpreted in terms of downwind variations.

The coarse trend spans a wide range of Md values, from 200 mm to 6 μm , and shows a

general decrease in Md with distance from source at a rate correlated with the eruption plume height (Fig. 2E). This correlation is valid for magmatic eruptions only. The deposits from phreatomagmatic eruptions follow a different pattern and show little grainsize change with distance (Figs. 3 and 4). This has been demonstrated using a compilation of bulk (i.e., non-deconvolved) grainsize data (Osman et al., 2020). Within a given range in plume height (Fig. 4), magmatic eruptions display decay trends that reach Md values of 100 μm at increasing distances from vent with increas-

ing plume heights (Fig. 3). This means that at a given distance from vent, tephra-fall deposits show decreasing Md values (on average) with decreasing plume height, which is well demonstrated by the boxplots in Figure 4. Most deposits from eruptions with plume heights of <10 km are unimodal, with Md grouping along a similar trend with distance from source (Fig. 3D). While there are more bimodal deposits for eruptions with plume heights of 10–20 km and 20–30 km, the unimodal Md and coarse Md again show similar decay trends with distance from source (Figs. 3B and 3C). For eruptions

with plume heights of >30 km above vent, two parallel coarse trends with similar decay rates are distinguishable (Fig. 3A). The upper trend is described by the Md data from the Taupo deposit at distances of <200 km from vent and the Campanian and Mazama deposits at distances of >500 km from vent. In this upper trend, Md values of 100 μm are observed ~800 km from vent (Fig. 3A). The lower trend consists of the Md data from the Rungwe and Huaynaputinia eruptions at distances of <100 km from vent and the Pinatubo, Minoan, and Tabora eruptions at distances of >100 km from vent. In this

Figure 4. Plots show distributions of median diameter (Md) in the coarse and fine trends as a function of distance from vent (horizontal panels) and maximum plume height above vent for magmatic eruptions. The coarse trend is defined by the unimodal GSDs excluding the distal unimodal ones, and coarse subpopulations. The fine trend is defined by the fine subpopulations. The phreatomagmatic eruptions are counted separately and represented by white boxplots. The distributions are represented by Tukey whiskers plots, where the thick middle line is the median, and the box spans the interquartile range (25th and 75th percentiles). The lower and upper whiskers show the smallest and largest values no farther than $1.5 \times$ the interquartile range (i.e., distance between the first and third quartiles). Outliers are plotted individually. Statistical parameters are summarized in Table S3 (see footnote 1).

lower trend, Md values of 100 μm are observed ~400 km from vent (Fig. 3A).

In most deposits for each plume-height category, we observe that the coarse trend reaches a plateau in Md distally, where Md remains constant with distance from vent around a grainsize value that varies among plume height categories (Fig. 3). These results indicate that at a given distance from source, the median grainsize in the coarse trend is correlated with the type (magmatic versus phreatomagmatic) and the intensity of the eruption, with coarser deposits at a given distance resulting from higher intensity magmatic eruptions. This behavior is less obvious (1) at very proximal distances from vent (<10 km), where we observe some overlap among magmatic deposits (Fig. 4), which highlights that a wide range of eruptions can deposit particles of similar grainsize at such close distances from vent, and (2) for eruptions with plume heights of >30 km above vent, which deposit a wide range of grainsizes at a given distance (see the wider boxplots for this plume height category in Fig. 4).

The fine trend spans a narrow range of Md values, from 200 μm to 2 μm (except for two values between 700 μm and 800 μm), and shows a very shallow decrease in Md with distance from source (Figs. 2 and 3). Two subparallel trends are apparent (Figs. 2E and 4). The coarsest trend mostly includes the fine subpopulations of the bimodal deposit from the Plinian 1845 Hekla eruption (Fig. 3B), which remains constant with distance with an Md value of 100 μm . The finest trend (<63 μm) mostly includes deposits from eruptions with high intensities (plume heights of >10 km). A slight decrease in Md in this trend is most apparent at distances of 10–100 km from vent (Figs. 2 and 4), while at distances of >100 km from vent, very little change in the fine trend of Md can be observed, with Mds of between 10 μm and 40 μm (Fig. 4 and Table S1).

The distal unimodal trend, mostly seen in deposits from eruptions with plume heights of >30 km (except for the 18 May 1980 Mount St. Helens eruption, whose plume height was between 20 km and 30 km above vent, Fig. 3B), spans a narrow range of Md values, from 100 μm to 15 μm , and shows little variation with distance from source (Fig. 2D).

A common pattern can be identified in the downwind variations of the grainsize: the steep decay of the coarse trend and the shallow decay of the fine trend meet in distal areas, where the distal unimodal trend is found (Figs. 2–4). The fine trend meets the distal unimodal and coarse trends between 500 km and 1000 km from vent (Figs. 2 and 3). The convergence in modes with distance

from vent has been identified in some tephra-fall deposits from ignimbrite-forming eruptions (Sparks and Huang, 1980; Brazier et al., 1983; Sparks et al., 1983; Engwell et al., 2014) and from lower intensity eruptions (Eycheenne et al., 2012, 2015; Engwell and Eycheenne, 2016). Based on the data compiled here, we demonstrate that the spatial variation patterns of the coarse and fine subpopulations follow universal behavior.

What Grainsizes Go Where?

Examining the distribution of Md at various intervals from source (Fig. 4 and Table S3) allows identification of spatial variation patterns among tephra-fall deposits. Because we are analyzing Md sizes, i.e., the median of the size distribution of grains at a given location, our data cannot be interpreted in terms of maximum grainsize transported. In fact, both coarser and finer material are present in the tephra samples. Given that we are working on deconvolved GSDs, we can be confident that the Md refers to a unique mode of the distribution and that the Md values are robust proxies of the most frequent grainsize found at the sampled locations.

Up to distances of 100 km from vent (Fig. 4), the Mds of the GSDs observed in fall deposits range from lapilli (64–2 mm) to fine ash sizes (<63 μm). At 50–100 km from vent, only eruptions with plume heights of >30 km above vent still deposit particles of lapilli-sized Md. Eruptions with lower plume heights deposit particles in the ash-sized range. Further than 100 km from vent, the deposits have an ash-sized Md ranging from coarse (2 mm to 63 μm) to fine ash (<63 μm). Interestingly, fine ash is deposited at all distances from vent for most eruption intensities (Fig. 4). At distances of <10 km from vent, only deposits from eruptions with the greatest plume heights (>30 km) lack fine subpopulations and hence a fine trend (Fig. 4). This reflects a lack of proximal measurements for these examples in our data set rather than an absence of bimodal deposits within this category at these distances.

The data presented here relate to distinct deposits that are identifiable by eye and do not include more diffuse deposits that can only be sampled as cryptotephra (Ponomareva et al., 2015; Stevenson et al., 2015; Cashman and Rust, 2020). However, the information can be used to inform the distances at which identifiable deposits occur for different eruption types (Fig. 4), similar to results using deposit thickness in Mahony et al. (2016). At distances of >500 km from vent, some grainsize information exists for eruptions with plume heights of >10 km above vent, but mostly for eruptions with plume

heights of >30 km (Fig. 4). Eruptions with intermediate plume heights tend to have grainsize data extending to distances between 200 km and 500 km from vent (Fig. 4). Eruptions with smaller plume heights tend to show observable deposits to a maximum distance of 200 km from vent (Fig. 4). These distances could be inferred to represent the locations at which distinct ash clouds are present in the atmosphere; however, particles are likely to travel as dilute clouds farther than the maximum distances inferred here and are deposited as cryptotephra (Cashman and Rust, 2020; Gouhier et al., 2019).

DISCUSSION

Origin of the Bimodality in Tephra-Fall Deposits

Our work indicates that two main categories of tephra-fall deposits exist: those dominated by unimodal GSDs and those dominated by bimodal GSDs (Fig. 2). Our analysis shows that deposits dominated by bimodal GSDs are from high-intensity eruptions (plume heights of >10 km, Figs. 2C and 2D), while deposits dominated by unimodal GSDs occur for a wide range of eruption intensities (Figs. 2A and 2B). The absence of bimodality, and hence fine subpopulations, in deposits from low-intensity eruptions (plume heights of <10 km; Table 1) can be attributed to the small amounts of fine ash produced by these eruptions. In our data set, these eruptions are typically lava-fountaining in type and therefore have low fragmentation efficiency (Rust and Cashman, 2011). Most phreatomagmatic deposits are unimodal in our data set (Fig. 3E), but this is not universal behavior. Other phreatomagmatic deposits from high-intensity eruptions that are not included here show evidence of bimodality (e.g., Tierra Blanca Joven, El Salvador [Pedrazzi et al., 2019]; Taupo Hatepe, New-Zealand [Walker, 1981]; and Soufriere St. Vincent, 1979 [Brazier et al., 1982]). We can thus conclude that there is no relation between the unimodality or bimodality of a tephra-fall deposit and the involvement of water in the fragmentation process.

Our analyses shows that high-intensity eruptions, which have high fragmentation efficiencies and thus the potential to produce fine, ash-rich plumes, can form both deposits dominated by unimodal GSDs and deposits dominated by bimodal GSDs. This demonstrates that the bimodality of fall deposits is not solely caused by source processes and that transport and deposition processes also play an important role. Previously, the presence of a prevalent fine grainsize subpopulation in tephra-fall deposits has been related to a contribution of fine ash

from co-pyroclastic density current plumes (co-PDC, i.e., plumes generated by the lift-off of PDCs during their emplacement). Evidence for such processes has been observed (1) in detailed sedimentological studies of individual tephra-fall deposits (e.g., Campanian ignimbrite, Minoan ignimbrite, 800 yr B.P. Quilotoa, 1974 Fuego, 1980 Mount St. Helens, 2006 Tungurahua; Sparks and Huang, 1980; Di Muro et al., 2008; Rose et al., 2008; Eychenne et al., 2012; Engwell et al., 2014; Eychenne et al., 2015), (2) as well as in a compilation of numerous deposits for which there is record of co-PDC plume formation (Engwell and Eychenne, 2016). This relation was demonstrated based on the comparison between the grainsize of distinct co-PDC deposits and the fine subpopulation of bimodal GSDs, as well as the geometry of the bimodal fallout deposits and the spatial prevalence of the fine subpopulation (Engwell and Eychenne, 2016). However, several of the tephra-fall deposits dominated by bimodal GSDs analyzed in this study are not thought to be associated with PDCs (Fig. S3 and Table S2), namely the 1845 Plinian Hekla eruption (Gudnason et al., 2018) and the 1991 Plinian Cerro Hudson eruption (Scasso et al., 1994). Other potential fine ash contributors to fall deposits that have been invoked to explain bimodality (Gudnason et al., 2018; Janebo et al., 2018), are (1) fine ash from waning or ash-venting eruption phases, which have lower energy and disperse tephra at low altitudes, hence depositing fine ash at the same distances from vent as coarser material from the climatic phase, and (2) syn- and post-eruptive wind remobilization of the contemporaneous fallout deposits, which is a size-selective process responsible for the resuspension and redistribution of fine ash only (Liu et al., 2014). Another potential process of fine ash enrichment of fall deposits is related to the late settling of co-Plinian ash. This term was first defined by Fierstein and Hildreth (1992) in the context of the multiple episodes of the 1912 Plinian Novarupta eruption. Fierstein and Hildreth (1992) describe fine ash that remains aloft after energetic Plinian phases, due to their low terminal velocities, and ends up mixed in with the deposits of subsequent explosive phases. Using the change in magma chemistry that occurred during the eruption, they demonstrated that as much as 4.5% and 12.5% of the fallout volume from the first, largely unimodal, Plinian rhyolitic episode was found in the dacitic fallouts from the second and third Plinian episodes, respectively, which both show bimodality (Fierstein and Hildreth, 1992). Mixing of co-Plinian and co-PDC ash was also proposed to explain the fine contribution in the 800 yr B.P. Quilotoa and Campanian Ignimbrite tephra-fall deposits (Perrotta and Scarpati, 2003;

Di Muro et al., 2008), which both have marked bimodality.

Bimodality of fall deposits can also be explained by some mechanisms that enhance the deposition of fine ash in proximal to medial locations. In fact, this is the most commonly invoked process to interpret tephra-fall deposits dominated by bimodality or the occurrence of bimodal GSDs in deposits otherwise dominated by unimodal GSDs (e.g., Carey and Sigurdsson, 1982; Brazier et al., 1983; Bonadonna et al., 2002b, 2011; Gudnason et al., 2017). Such enhanced deposition mechanisms include (1) ash aggregation (Brown et al., 2012), by which small particles cluster together to form a bigger grain with higher settling velocity (Carey and Sigurdsson, 1982), or small particles coat coarser grains and are thus scavenged from the plume (Bagheri et al., 2016), or hydrometeors induce particle aggregation and settling (Durant et al., 2009; Van Eaton et al., 2015; Gudnason et al., 2017); (2) en-masse settling due to gravitational instabilities (Carazzo and Jellinek, 2013; Manzella et al., 2015); and (3) fine ash entrainment in the tail of bigger grains by a process called wake capture (Lovell and Rose, 1991). All of these processes will be discussed in the next section in relation to the grainsize trends, but they are most prominent in high-concentration plumes. During the 18 May 1980 Mount St. Helens eruption, which produced a strongly bimodal deposit, coarse and fine ash were documented falling concomitantly by syn-eruptive time series sampling, which led to bimodal grain sizes (Scheidegger et al., 1982). Ash clusters were also observed and sampled syn-eruptively for the first time (Sorem, 1982).

Another well-known process that creates polymodality in tephra deposits is a change in wind direction during eruptions. The resulting shift in the plume dispersal axis generates a shift in the tephra depositional axis, leading to overlapping particle sizes on the ground. Such a process was well described during the 2008 long-lasting eruption of Chaiten (Watt et al., 2009) and is generally accompanied by multilobate fall deposits.

This grainsize compilation suggests that both a high fine ash content and enhanced deposition processes are prerequisite conditions for generating deposits dominated by bimodality, while deposits dominated by unimodal GSDs but displaying scattered subordinate bimodal samples could solely result from enhanced fine ash deposition without requiring an additional source of fine ash. For example, the 17 June 1996 Ruapehu eruption (Table 1, Fig. 3) generated several bimodal samples despite the deposit being dominated by unimodal GSDs and produced less than 5 wt% of fine ash as inferred from one of the most comprehensive TGSD reconstructions in

the literature (Bonadonna and Houghton, 2005). The data presented here show that the Ruapehu grainsize decay plateaus around 100 μm in distal areas (>100 km from vent; Fig. 3D), which confirms that a small amount of fine ash was available during this eruption. On the contrary, all of the deposits dominated by bimodality in our data set were generated by eruptions for which prominent secondary sources of fine ash exist (Table S2). Even the 1845 Hekla and the 1991 Cerro Hudson deposits (Figs. 3B and 3C), which are not considered to be associated with large PDCs and therefore are not enriched by co-PDC ash, have other secondary sources of fine ash. In the case of the 1845 Hekla event, witness accounts describe late settling of fine particles (Gudnason et al., 2018), which could be related to the settling of co-Plinian ash or ash from a waning or ash-venting phase after the main Plinian event. Additionally, wind erosion and remobilization of the tephra-fall deposit were also described after this event (Gudnason et al., 2018). In the case of the 1991 Cerro Hudson eruption, consistently strong winds, combined with pulsatory eruptive activity (Scasso et al., 1994), promoted the mixing of co-Plinian ash with tephra from succeeding phases.

Physical Controls on the Spatial Grainsize Trends

Our work highlights two major findings: (1) all of the tephra-fall deposits contribute to two distinct trends of grainsize decay, coarse and fine, which converge in distal regions where they reach similar grain sizes (Figs. 2 and 3), and (2) a relation exists between the patterns of grainsize decay in the coarse trend and the eruption intensity (plume height; Fig. 4). Here, we discuss the physical controls on these two main results.

Controls on the Coarse and Fine Trends: Differences in Sedimentation Behavior

The steep grainsize decay with distance from vent in the coarse trend, and the shallow grainsize decay in the fine trend (and the phreatomagmatic deposits), are related to the contrasting settling mechanisms controlling the sedimentation of coarse and fine particles. The coarse decay is well explained in the literature by individual particle settling at terminal fall velocity using different physical models (e.g., Walker et al., 1971; Brazier et al., 1982; Carey and Sigurdsson, 1986; Carey and Sparks, 1986; Sparks et al., 1992; Rose, 1993; Eychenne et al., 2017). Based on the thickness trends with distance, settling regimes for individual particles and sedimentation laws have been determined (Fierstein and Hildreth, 1992; Hildreth and Drake, 1992; Rose, 1993; Bonadonna et al.,

Figure 5. Thickness and median grainsize are plotted versus distance for some key examples. For grainsize information, see Table S1 (see footnote 1). Thickness data are from Engwell et al. (2014), Sarna-Wojcicki et al. (1981), McGimsey et al. (2001), and Edwards et al. (2018).

1998). Bonadonna et al. (1998) showed that three breaks in slope can be identified in the thinning rates of tephra-fall deposits. While the most proximal change in slope is related to the transition from column margin to umbrella cloud fallout (see data for Mt. Spurr in Fig. 5), the other two breaks in slopes are interpreted as resulting from the particles' settling regime changing as the plume disperses away from vent. This is a consequence of a decrease in the Reynolds number of the particles, which is mostly related to a decrease in particle grain-size (Rose, 1993), which leads to transitions in particle settling regimes from turbulent (lapilli range), to transitional (coarse ash range), and laminar (fine ash range).

In many of the deposits compiled here, breaks in slopes are observed in the grainsize decay of the coarse trend with distance (Figs. 5 and S3), mimicking the changes identified in the thinning rates of fall deposits by Bonadonna et al. (1998). A steep decline of the grainsize decay is observed close to source, and a shallower decay is observed at greater distances: e.g., Askja D, Hekla 1947; Spurr, Tungurahua, Hekla 1991; Etna January 2011 (Figs. S3 and 5). The first break in slope occurs roughly at grainsizes around 10 mm (abrupt change) and the second sometimes identifiable break in slope is around

100 μm (more gradual change). Based on the theory of particle settling, these breaks in slopes can be related to the transition from turbulent to transitional and transitional to laminar settling regimes, respectively (Bursik et al., 1992; Ganser, 1993; Bagheri and Bonadonna, 2016). However, applying the particle settling scheme of Ganser (1993) to the August and September 1992 Spurr eruptions, Eycheenne et al. (2017) demonstrated that in medial to distal areas, the shallow decay theoretically generated by particles falling in the laminar regime departs from the individual settling decay. This was also identified and discussed in other deposits (e.g., 2011 Cordón Caulle and 1980 Mount St. Helens eruptions; Durant et al., 2009; Rose and Durant, 2009; Bonadonna et al., 2015b). This implies that sedimentation in the depositional areas where grainsize and thickness show very little change with distance (i.e., the sedimentation of particles roughly below 100 μm) is controlled by a process other than individual settling.

Our compilation highlights that the shallow distal grainsize decay is the continuation of a shallow and fine trend in proximal and medial areas, which is composed of the fine subpopulations of bimodal deposits and the phreatomagmatic deposits (Fig. 3). The deposition of the

fine subpopulation of bimodal deposits cannot be caused by individual particle settling, given that at the same distances the particles settling individually comprise the coarse trend (Carey and Sigurdsson, 1986; Sparks et al., 1992; Eycheenne et al., 2017). The questions raised by these observations are: (1) In proximal and medial areas of tephra-fall deposits, what are the processes controlling the sedimentation of fine ash (roughly below 100 μm) and generating the fine subpopulations of bimodal deposits and fine GSDs of phreatomagmatic deposits? (2) Are the same processes controlling the sedimentation of fine ash in distal areas and forming the distal unimodal deposits? These questions have been explored in the literature. It is anticipated that in proximal regions, both the high concentration of ash in the atmosphere and the wide range of particle sizes available can trigger aggregation (Brown et al., 2012) and other enhanced settling processes, such as hydrometeor formation (Durant et al., 2009; Van Eaton et al., 2015; Gudnason et al., 2017), deposition by gravitational instabilities (Carazzo and Jellinek, 2013; Manzella et al., 2015), and wake capture (Lovell and Rose, 1991). However, in more distal reaches, where volcanic plumes are more dilute and depleted in coarse material, processes triggered by particle interactions in highly concentrated mixtures, or by fine particle entrainment in the wake of coarse grains, are less likely to occur. Yet, even in distal ash clouds, fine ash particles can interact to form loose ash clusters (Sorem, 1982; Brown et al., 2012), and there is evidence of aggregate types changing from proximal (accretionary pellets) to distal (ash clusters) locations in individual fallout deposits (Brown et al., 2012). Additionally, atmospheric processes could be critical in controlling deposition of fine ash in distal areas. Vertical variations in atmospheric turbidity, humidity, and temperature can modulate the efficiency of aggregate and hydrometeor formation (Durant and Rose, 2009; Durant et al., 2009), while wind shear, convection, and orographic effects are also major controls on fine ash distribution and deposition (Eycheenne et al., 2017; Poulidis et al., 2018). These different atmospheric processes, as well as the physico-chemical characteristics of the ash particles (i.e., density, texture, and shape), which strongly affect their transport and sedimentation behavior (Saxby et al., 2020), are all likely to make individual settling irrelevant for the deposition of fine ash.

To conclude, the distinctive coarse and fine grainsize decay observed in tephra-fall deposits provides evidence of the decoupled settling behavior between particles in the lapilli and coarse ash range and particles in the fine range. This leads to decoupled sedimentation behaviors in proximal/medial and distal areas.

The deposition of fine ash itself does not result from a single ubiquitous process but is likely different in proximal and distal locations and sensitive to atmospheric conditions and particle characteristics.

Controls on Grainsize Decay Rates: Competition between Eruption Dynamics and Transport Processes

The patterns of grainsize decay in the coarse trend appear to be related to the eruption dynamics through the mass eruption rate (i.e., intensity), which is represented here by the maximum plume height above vent (Figs. 3 and 4). The decay in the coarse trend can be described in terms of (1) rate of decay (rate at which the grainsize decreases with distance from vent), and (2) position of the decay (grainsize found at a given distance from vent). This is evident when comparing eruptions with different intensities but parallel decay trends (Fig. 2E). In the case of magmatic eruptions, both are correlated with the plume height (Fig. 3). The correlation between decay rate and plume height means that the Md of tephra-fall deposits decreases more rapidly with distance from vent for high-intensity magmatic eruptions than low-intensity magmatic eruptions or phreatomagmatic eruptions (Fig. 3). The correlation between position of decay and plume height translates to the presence of coarser particles at a given distance (Fig. 4), and wider deposit extents, for more intense eruptions. Note for example the distance from vent at which the average grainsize of the deposits get below 100 μm in Figure 3.

The decay rate is theoretically related to the time it takes the particles to be transported and to settle through the atmosphere, and hence to particle transport and sedimentation mechanisms (Carey and Sparks, 1986; Pyle, 1989). These processes are mainly controlled by the type of settling mechanisms (individual or collective settling), the characteristics of the particles available for fallout in the plume (size, density, and shape), gravity current momentum in proximal areas, and wind velocity and other atmospheric processes. This latter dependence on atmospheric conditions explains the variability observed between decay rates within plume-height categories (Fig. 3). For example, the decay trend from the Pululagua eruption appears steeper than the rest of the coarse trend in Figure 3B and corresponds to a circular tephra-fall deposit (Volentik et al., 2010), which means that it was generated by a plume dominated by gravitational spreading and was not significantly affected by wind advection. The general increase in grainsize decay rate with increasing plume height (Figs. 2E and 3) could thus be explained by the larger effect of gravity spread-

ing on the settling mechanisms of high intensity eruption plumes. Overall, the steep decay rates encountered in fall deposits from high-intensity eruptions reflect a high settling efficiency of particles in the plumes, which was previously demonstrated based on the lower proportion of far-traveled fine ash observed in high-intensity eruption plumes by satellite retrieval methods (Gouhier et al., 2019).

The position of the decay should be related to the grainsize distribution of the material available for fallout in the plume (specifically the maximum grainsize and the amount of fine ash) and the height of particle release (i.e., plume height). Indeed, the finer the grainsize distribution and the higher the particles released, the further they can be transported (Carey and Sparks, 1986; Pyle, 1989). The grainsize distribution of particles within the initial plume is controlled by the efficiency of fragmentation and the mass eruption rate. The higher the fragmentation efficiency, the higher the amount of fine ash produced (Cashman and Scheu, 2015), and the higher the mass eruption rate, the coarser the maximum tephra grainsize entrained and the higher the plume (Carey and Sparks, 1986). Fragmentation efficiency and mass eruption rate are strongly related, which explains why such a strong positive correlation between the position of decay and the maximum plume height above vent is observed in our data (Figs. 3 and 4).

To conclude, the patterns of grainsize decay are controlled by both transport mechanisms and source processes (i.e., the eruption dynamics, e.g., fragmentation, mass eruption rate, and height of particle release). The competition between transport and source processes controls the spatial grainsize variations in tephra-fall deposits.

Implications for Ash Transport in Distal Reaches

We demonstrate that tephra-fall deposits in distal areas show characteristic grainsize variations, regardless of eruption dynamics, whereby grainsize distributions are unimodal and show no change in Md with distance from vent (Figs. 2 and 3). This has been documented in deposits from large explosive eruptions such as the Campanian Ignimbrite, the Mazama, and Tambora 1815 eruptions (Kandlbauer et al., 2013; Engwell et al., 2014; Engwell and Eychenne, 2016; Buckland et al., 2020). We also show that the median grainsize in distal fall deposits, and the distance at which a deposit can be considered to be distal, vary among case studies and are strongly correlated to eruption intensity (Figs. 3 and 4). Most tephra deposits from eruptions with smaller (<10 km) plume heights

extend less than 60 km from vent and never see their median grainsizes become constant or go below a value of 100 μm , apart from the January 2011 Etna eruption, which reaches a clear plateau at a Md value of 115 μm between 60 km and 100 km from vent (Fig. 3D). Deposits from eruptions with moderate plume heights (10–20 km) plateau between 100 km and 300 km from vent, at Md values of between 100 μm and 50 μm (Fig. 3C). In eruptions with large plume heights (20–30 km), the distal deposit behavior is observed 200–500 km from vent at Md values of <50 μm (Fig. 3B), while for eruption deposits from very large plumes (>30 km), the transition is observed beyond 600 km from vent, at Md values of <50 μm (Fig. 3A).

The first implication of these findings is that, based on this grainsize pattern, it is possible to use objective and systematic criteria to identify “distal” areas of tephra-fall deposits. Indeed, the term “distal” is used ubiquitously in the description of volcanic deposits; however, it is rarely described in a quantitative way. We propose that the term “distal” be used where the grainsize of ash plateaus. The use of our criteria will allow fall deposits to be compared more effectively and better interpretation of the dispersion and sedimentation processes in play.

Our analyses of a comprehensive suite of fall deposits reinforce the previously reported observation that in distal areas, particles do not settle as individual particles due to their small sizes (<100 μm). Distal deposits represent what is left in the plume after particles that settle according to their terminal velocities have already been deposited. Given that distal plumes have rather low concentrations, fine ash must reach the ground in distal areas because they are coupled to atmospheric flows (Eychenne et al., 2017; Poulidis et al., 2018, 2021) or due to loose aggregation (Brown et al., 2012). Quantifying the contribution of these processes in distal settling is challenging. But our data demonstrate a relation between the median grainsize of distal deposits and the eruption intensity (Fig. 3), which shows that eruption characteristics are key in controlling ash sedimentation in distal reaches. In distal deposits from low-intensity eruptions (plume height of <10 km), the absence of fine ash in high amounts at the source means that a plateau in grainsize is rarely seen, and when it occurs, it is in the coarse ash-size range (Md of \sim 100 μm). The contrasting grainsizes observed in distal deposits from eruptions with plume heights of >30 km above vent, compared to plume heights between 20 km and 30 km (40 and 25 μm , respectively; Fig. 3), could be predominantly controlled by the shape and textural properties of the grains (Riley et al., 2003; Saxby et al., 2018). Indeed, eruptions with plume heights of

>30 km have extremely high intensities and tend to fragment highly vesicular magma and generate ash dominated by extreme shapes such as platy glass shards (Rose and Chesner, 1987; Engwell et al., 2014). These particles have low terminal velocities (Saxby et al., 2020), which means that 40 μm particles may be roughly aerodynamically equivalent to 25 μm particles with more standard shapes. This would lead to a relatively coarse grainsize threshold ($\sim 40 \mu\text{m}$), below which individual settling becomes irrelevant, and to relatively coarse-grained distal deposits.

The major implication of these results is that processes not yet well understood control the dispersion and sedimentation of fine ash in distal reaches, and consequently the amount of fine ash that remains suspended in the atmosphere, where it is capable of traveling great distances. Far-traveled ash is a critical hazard in volcanology because of the severe impacts it has on (1) aviation, with disruption to air traffic and the potential for substantial economic loss (Budd et al., 2011), and (2) air quality, with potential adverse health effects (Horwell and Baxter, 2006; Carlsen et al., 2015) even at distances from vent of >1000 km (Balsa et al., 2016). There is discussion in the volcanology community about the size and amount of ash that reaches great distances, which varies depending on the records used, and in particular how information from tephra-fall deposits, satellite ash retrievals, and cryptotephra can be used together (Stevenson et al., 2015; Cashman and Rust, 2020; Gouhier et al., 2019). Deposit and cryptotephra records report coarser grainsizes than satellite data at the same distances from vent (Stevenson et al., 2015). The discrepancy between what is measured in the atmosphere and what is measured on the ground is difficult to resolve, given the fundamental differences in measurement methods and the limits of satellite ash-retrieval techniques (Stevenson et al., 2015). Here, we suggest using the constant and ubiquitous grainsizes observed in distal deposits as a benchmark to refine satellite ash-retrieval methods. As mentioned before, deposits and cryptotephra do not describe the same portion of the drifting ash plume, and we can suppose that cryptotephra are the continuation of distal tephra-fall deposits. The grainsizes measured in these two records should be carefully compared, as has been done in a few cases (Stevenson et al., 2015; Cashman and Rust, 2020), to understand the behavior of dilute ash clouds in ultra-distal reaches.

Implications for the Use of Tephra-Fall Deposit Records

Tephra-fall deposit records are used to interpret the dynamics (magnitude and intensity) of

volcanic eruptions, specifically past eruptions that were not witnessed (e.g., Walker, 1973; Pyle, 1989; Bonadonna and Costa, 2013). They are also widely used as benchmarks for validating numerical models of tephra transport and deposition (e.g., Bonadonna et al., 2005; Folch et al., 2010; Woodhouse et al., 2013). These different applications have predominantly relied on thickness data and on trends of thickness variations with distance. When tephra thickness versus distance variations are compared to grainsize decay with distance, very similar trends are observed (i.e., steep decline in both grainsize and thickness close to source, with a levelling out at greater distances; Fig. 5). In most examples, the magnitude of change in grainsize over the extent of a deposit is comparable to that of tephra thickness. For a given eruption, the variability in grainsize at a given distance from source is considerably less than the variability in thickness (Fig. 5). Analysis of thickness and grainsize information from the Campanian Ignimbrite eruption showed that higher thickness variability was related to depositional environment and secondary processes such as deposit remobilization and sedimentation (Engwell et al., 2014), with a comparatively smaller effect on deposit grainsize. Grainsize decay trends are excellent indicators of tephra transport and sedimentation processes. We thus argue that grainsize data provide a robust parameter for validating numerical model results, and that thickness and grainsize trends should be used conjointly.

CONCLUSIONS

We present an unprecedented data set compiling grainsize information for 56 tephra-fall deposits. This data set allows the inter-comparison of grainsize characteristics of fall deposits generated by eruptions of low to high intensities and magnitudes.

We highlight that fall deposits can show scattered or ubiquitous grainsize bimodality or unimodality. We demonstrate that deposits dominated by bimodal GSDs result from a high fine ash content at the source and enhanced deposition processes, while deposits displaying scattered subordinate bimodal GSDs result from local enhanced fine ash deposition processes.

We identified universal grainsize trends with distance from vent, whereby all tephra-fall deposits contribute to one of two distinct trends of grainsize decay: a coarse trend decreasing with distance from vent and a fine trend showing little change with distance. Both trends converge with distance in distal regions, where they reach a plateau of constant grainsize. These decoupled coarse and fine trends result from particle size-

dependent contrasting sedimentation behaviors. In the lapilli and coarse ash size range, tephra sedimentation is dominated by individual particle settling at terminal fall velocity. In the fine ash size range, a combination of mechanisms is in play, from aggregation and other collective settlings to particle coupling with atmospheric flows. The contribution and relevance of these different processes are difficult to quantify, but we show that they do not have a particle size-fractionation effect with distance from vent for particles sub ~ 100 microns. This leads to constant grainsizes in distal reaches of fall deposits, due to a depletion of the plume in particles capable of settling individually at such distances from vent.

We demonstrate that a correlation exists between plume height and grainsize decay in the coarse trend. This translates into larger M_d at a given distance from vent for increasing eruption intensities and suggests that fragmentation and eruption dynamics at the vent (mass eruption rate) explain most of the variability among fall deposits from eruptions of different sizes, which overprints the effects of transport processes.

Our findings have implications for understanding the behavior of far-traveled volcanic ash, which is a major hazard that impacts aviation and health, and for improving the usage of tephra-fall deposit records. Further work is needed on employing records of observable tephra-fall deposit and cryptotephra to decipher the dispersion and sedimentation of volcanic ash at great distances from vent. We propose greater use of grainsize distribution data in addition to maximum grainsize and thickness data for interpreting deposits in terms of eruption dynamics and for validating numerical models of tephra transport and deposition.
