| 25 | isotopes of the Ampato-Sabancaya compound volcano, which belongs to the Andean |

Central Volcanic Zone (CVZ). Whole-rock compositions for Ampato and Sabancaya 26 range from andesites to dacites (56.7-69.3 wt.% SiO₂) and both belong to a medium- to 27 high-K calk-alkaline magmatic series. Ampato-Sabancaya samples are characterised by 28 high contents of large-ion lithophile elements (LILE; e.g., K, Rb, Ba, Th), low 29 30 concentrations of high field strength elements (HFSE; e.g., Nb, Zr) and heavy rare earth 31 elements (HREE; e.g., Yb), with consequently high La/Yb and Sr/Y ratios. An increase in these ratios is usually interpreted as a result of magmatic differentiation in the 32 33 presence of garnet in the deep crust. A detailed analysis reveals that the rocks of Ampato-Sabancaya display three different compositional groups. (1) The first, composed mainly 34 of andesites (56.7–59.8 wt.% SiO₂), corresponds to lavas from the early stage of the 35 36 Ampato Basal edifice, as well as pyroclastic deposits from the Ampato Upper edifice. (2) The second group corresponds to andesitic and dacitic compositions 37 (60.0-67.3 wt.% SiO₂) from the Ampato Basal edifice (Moldepampa stage), the 38 Ampato Upper edifice, and the Sabancaya edifice. (3) The third group corresponds to 39 dacitic compositions (65.0-69.3 wt.% SiO₂) associated with the Corinta Plinian fallout 40 41 and pyroclastic flow deposits from the Ampato Upper edifice. This last group of dacites, erupted during the Ampato Upper edifice stage, have drastically different compositions 42 from the other groups with Sr/Y (<27) and Sm/Yb (<4.7) ratios lower than other lavas 43 44 and lacking evidence of amphibole and/or garnet fractionation during their genesis. As a whole, Sr, Nd, Pd isotopic ratios suggest that mantle-derived magmas are significantly 45 affected by assimilation processes during their evolution, due to the thick (65–70 km) 46 continental crust beneath the CVZ in southern Peru. In summary, the magmatic 47 evolution of group 1 and 2 can be explained by a two-step model in which primitive 48 magmas evolved in the deep crust in the so-called melting-assimilation-storage-49 homogenization (MASH)-type reservoirs by assimilation-fractional crystallization 50

(AFC) processes involving garnet and/or amphibole. Then, amphibole-dominated upper crustal AFC processes and magma mixing are responsible for the geochemical diversity of the main ASCV trend. In contrats, the group 3 dacites followed an upper crustal AFC process (without amphibole) from a different primitive magma, which did not suffer the high pressure, garnet-dominated AFC processes. This evolution highlights the complexities associated to magma genesis and differentiation at continental arcs contructed on a thick crust.

61

62 1. Introduction

The volcanic arc along the Andean Cordillera results from the subduction of the 63 oceanic Nazca plate below the continental South American plate. This volcanic arc is 64 divided into three active arc segments, the Northern (NVZ), Central (CVZ), and Southern 65 (SVZ) volcanic zones (Fig. 1a). In addition, the Austral volcanic zone (AVZ) results from 66 subduction of the Antartica plate below the South American plate. The CVZ is composed 67 68 of volcanoes in southern Peru, Bolivia, and northern Chile and Argentina. This arc segment is constructed on one of world's thickest continental crusts and is considered the 69 70 archetype for studying crustally-modified arc magmas (Barreiro and Clark, 1984; 71 Harmon et al., 1984; Thorpe et al., 1984; Davidson et al., 1991; Mamani et al., 2010).

Quaternary lavas in the CVZ are high-K andesites, dacites and rhyolites that systematically display low heavy rare earth elements (HREE) and Y contents. In addition, these magmas are characterised by high 87 Sr/ 86 Sr and 18 O ratios (typically >0.70534 and 75 8–12‰, respectively), low ϵ Nd (-2–12), and relatively low 206 Pb/ 204 Pb ratios (17.3–19.0) (Barreiro and Clark, 1984; James, 1982; Wörner et al., 1988; Davidson et al., 1991; Haschke et al., 2006; Delacour et al., 2007; Kay et al., 2010; Mamani et al., 2010; Rivera et al., 2017). Petrogenetic models for the CVZ consider that the primitive calc-alkaline magmas are derived from partial melting of a mantle wedge previously metasomatised by hydrous fluids released through dehydration of the subducted lithosphere. These mantlederived magmas evolved by fractional crystallization coupled with crustal assimilation or partial melting during magma storage and ascent through the thick continental crust.

83 Given that the CVZ magmas have systematically high La/Yb, Sm/Yb and Sr/Y ratios, some researchers support the idea that evolution of these magmas is dominated by 84 crustal partial melting with garnet present in the residue (Kay, 2002; Mamani et al., 2010). 85 While other authors (e.g., Hildreth and Moorbath, 1988; Davidson et al., 1991; Freymuth 86 et al., 2015) consider that both mantle-derived and crust-derived magmas may have mixed 87 and/or mingled at deep levels in the high-pressure melting, assimilation, storage and 88 homogenization (MASH) zones, thereby producing large volumes of contaminated 89 andesitic magmas. This model has been corroborated through recent seismic imaging 90 91 studies that show low seismic velocity zones throughout the crust which are interpreted 92 as the upper part of trans-crustal MASH zones (Delph et al., 2017). As a complement of the MASH model, several studies highlight the role of low pressure AFC processes as an 93 explanation of the compositional diversity of magmas erupted at the large compound 94 CVZ volcanoes (e.g., James, 1982; Barreiro and Clark, 1984; Harmon et al., 1984; Thorpe 95 et al., 1984; Vatin-Pérignon et al., 1992; Feeley and Sharp, 1995; Godoy et al., 2014; 96 Rivera et al., 2017). Recently, Blum-Oeste and Wörner (2016) proposed a slightly 97 different model in which magma mixing (instead of the AFC process) is the dominant 98 process, and identified three geochemical end-members for the CVZ magmas: (1) a 99 slightly evolved calc-alkaline, mantle-derived basaltic andesite; (2) an enriched, mantle-100

derived, shoshonitic basalt; and, (3) a crust-derived rhyodacite. Following these authors,
the variable proportions of these three end-members could explain the compositional
variability of CVZ magmas.

In order to provide constraints on the crustal contribution of the CVZ magmas, we 104 focus on the petrogenetic evolution of a single volcanic centre of this arc segment, the 105 Ampato-Sabancaya compound volcano (ASCV), a large, late Pleistocene volcanic centre 106 of the Peruvian CVZ. Previous studies on this volcanic centre focused on reconstructing 107 108 the eruptive chronology and identifing a large magmatic diversity of silica-rich end-109 members (dacites and rhyolites) that could represent different modalities of the crustal processes (Samaniego et al., 2016; Rivera et al., 2016). Based on a detailed reconstruction 110 111 of the Ampato-Sabancaya eruptive chronology, we present major and trace element 112 compositions, and Sr, Nd, and Pb isotope data for samples covering the entire Ampato-Sabancaya lifetime. These data record the compositional variations through the evolution 113 of the Ampato-Sabancaya compound volcano and enable us to identify the main 114 petrogenetical processes that control the composition of the erupted magmas. These 115 116 hypotheses have been tested using different geochemical modelling approaches in order 117 to describe the evolution of magma genesis at ASCV during the last 0.5 My.

118

119 2. Regional geological setting

In southern Peru, the CVZ arc segment results from subduction of the 40–45 Ma oceanic Nazca plate beneath the South American continental plate at a convergence direction of N80° and rate of 5–7 mm/yr (Norabuena et al., 1998). The resulting volcanic arc developed along the Western Cordillera and is constructed on continental crust reaching ~65-70 km thick along the main Andean keel (Beck et al., 1996). Geological mapping of the Western Cordillera indicates that the oldest rocks correspond to granulite-

facies gneisses (such as the Charcani gneiss portion of the Arequipa Massif, Boily et al., 126 1989) that crop out 32 km northwest (in Colca Canyon) and 34 km southwest of Ampato-127 128 Sabancaya volcano. The Arequipa Massif includes rocks with protolith ages of 1.9 Ga (Dalmayrac et al., 1977) and others with Mesoproterozoic protoliths and metamorphism 129 ages of 1.2–1.0 Ga (Wasteneys et al., 1995; Loewy et al., 2004). These rocks arguably 130 occur at depth beneath the volcanic arc of southern Peru (Harmon et al., 1981). This older 131 massif is unconformably overlain by weakly folded, Mesozoic marine clastic (Yura 132 133 Group) and volcano-sedimentary formations that have been intruded by Paleogene granites and granodiorites belonging to the Coastal Batholith (Tiabaya super-unit; Caldas, 134 1973; Romero and Ticona, 2003). These formations are covered by Oligocene-Miocene 135 136 volcaniclastic and volcanic sequences (Tacaza Group) that in turn are overlain by Pliocene-Pleistocene volcanic sequences (Barroso Group). Late Quaternary volcanoes, 137 such as Ampato-Sabancaya, are constructed on top of a high-altitude plateau formed by 138 the older Barroso and Tacaza volcanic sequences. 139

The Quaternary volcanic arc in southern Peru is composed of at least 14 andesitic 140 141 and dacitic compound volcanoes and several monogenetic volcanic fields (de Silva and Francis, 1991; Siebert et al., 2010; Bromley et al., 2019) (Fig. 1a, b). During historical 142 time (*i.e.*, following the Spanish conquest beginning in 1532 CE), six of these volcanoes 143 144 have experienced eruptive activity: Sabancaya, El Misti, Ubinas, Huaynaputina, Ticsani, and Tutupaca (Thouret et al., 2005; Thouret et al., 2001; Siebert et al., 2010; Samaniego 145 et al., 2015). Some of these volcanoes experienced large explosive eruptions during the 146 last few millenia and historical times, including the Plinian eruptions of El Misti (c. 2030 147 yr BP, Thouret et al., 2001; Harpel et al., 2011), Ubinas (c. 1000 yr BP, Thouret et al., 148 2005; Samaniego et al., 2020), and Huaynaputina (1600 CE, Prival et al., 2020), as well 149 as the collapse-triggered explosive eruption of Tutupaca (1787–1802 CE, Samaniego et 150

al., 2015). In addition, Ubinas and Sabancaya are among the most active Central Andean
volcanoes, with several small-to-moderate magnitude eruptions during the last centuries.
The most recent such eruptions occurred during 2006–2009 CE, 2013–2017 CE and 2019
CE at Ubinas; and 1986–1998 CE and since 2016 CE at Sabancaya.

155

156 3. Ampato-Sabancaya volcanological evolution

The Ampato-Sabancaya compound volcano (ASCV, 15° 49.3'S, 71° 52.7'W) is 157 located 75 km northwest of the city of Arequipa (Fig. 1), in the Western Cordillera of the 158 Andean Central Volcanic Zone (CVZ, Fig. 1a). This compound volcano is situated 159 southeast of the older, Pleistocene, Hualca Hualca edifice (6,025 m above sea level -160 161 a.s.l.). Ampato (6,280 m asl) and Sabancaya (5,980 m asl) form a massif, aligned along a N50° trend, decreasing in age from SW to NE. An andesitic lava flow emplaced over 162 Pliocene ignimbrites forms the basement of the ASCV and has an age of 0.80 ± 0.04 Ma 163 (Gerbe and Thouret, 2004), constraining the initiation of growth for Ampato and 164 Sabancaya volcanoes to have been during the middle or upper Pleistocene. 165

166

Ampato volcano covers an area of 90–100 km² with an approximate volume of 38–42 167 km³ (Samaniego et al., 2016). The volcano's current morphology is formed by at least 168 169 three successive cones orientated SW-NE, hereafter termed the Southern, Central, and Northern cones, respectively located 1.2 and 2.5 km from the summit (the Southern cone) 170 (Fig. 2). Ampato was affected by glacial erosion during the Last Glacial Maximum 171 (LGM) which roughly occurred in this part of the Andes between 17 and 25 ka (Bromley 172 173 et al., 2009). On Hualca Hualca volcano, cosmogenic exposure ages on blocks from LGM moraines indicate that this event occurred between 16 and 17 ka (Alcalá-Reygosa et al., 174 2017). This glacial event generated a variety of morphological features such as circues 175

and U-shaped valleys on the western and southeastern flanks of Ampato. Following
Rivera et al. (2016) and Samaniego et al. (2016), the eruptive chronology of Ampato
compound volcano comprises:

(1) The Ampato Basal edifice (Fig. 2), which is an old, highly eroded volcano composed 179 of a 600-m-thick succession of lava flows interlayered with scarce scoria-flow deposits 180 (57.2–62.2 wt.% SiO₂) and spatter agglutinates that crop out on the proximal 181 southwestern and western flanks of Ampato (AMI-1, Fig. 2). We include in this older 182 183 stage, a 200-400 m-thick medial-to-distal succession of sub-horizontal andesitic lava flows (57.2-61.9 wt.% SiO₂) that crop out on the Jatun Pampa plain, on the southeast side 184 of Ampato (AMI-2, Fig. 2). This, the oldest stage of the Ampato Basal edifice, was 185 186 constructed between 450 ka and 400 ka (Samaniego et al., 2016). Another remnant of this edifice (Moldepampa stage, AMI-3, Fig. 2) consists of a 200–300 m-thick succession of 187 dacitic lava flows (62.9–65.1 wt.% SiO₂). Age determinations by Samaniego et al. (2016) 188 on lavas of this stage yield dates of about 230–200 ka. Samaniego et al. (2016) and Rivera 189 et al. (2016) assumed that a 4–5 m-thick succession of rhyolitic tephra-fall deposits (74.2– 190 191 76.9 wt.% SiO₂), which only crop out in the Chacramayo valley 10 km southwest of 192 Ampato, were emplaced at the end of this stage. In this work, we challenge the origin of these rhyolitic deposits. 193

(2) The Ampato Upper edifice started with the Yanajaja stage (AMII-1, Fig. 2), which consists of a succession of andesitic and dacitic lava flows (61.8-63.5 wt.% SiO₂) reaching 200–300 m thick that outcrop on the south and southwest flanks of Ampato. A sample from this unit was dated at 77 ± 4 ka. The successive construction of the Northern (AMII-2), Southern (AMII-3, 4, 6, 7), and Central (AMII-8) peaks is represented by lava flows and pyroclastic sequences with andesitic compositions (61.0-62.0 wt.% SiO₂). Two lavas of the south and southeast flanks of the Upper edifice yielded ages of 40 ± 3 and 34 ± 8

ka, respectively. Associated with this volcanic stage are the thick (>20 m) block-and-ash 201 flow deposits that crop out 5–6 km east and west of the Ampato summit (AMII-5, Fig. 202 2). In addition, we include in this stage the scoria-rich Baylillas (56.7–59.0 wt.% SiO₂) 203 and Corinta (65.0–68.0 wt.% SiO₂) tephra-fall and pyroclastic-density current deposits 204 which crop out 10-12 km southwest of the volcano's summit. These pyroclastic 205 successions are highly eroded and were likely emplaced before the LGM (i.e., 17–25 ka; 206 Bromley et al., 2009; Alcalá-Reygoza et al., 2017). The central cone was discordantly 207 208 constructed over the remnants of the northern and southern cones of the Ampato Upper edifice (Fig. 2). It is composed of a sequence of andesitic and dacitic (61.3-66.0 wt.% 209 SiO₂) lava flows, with a maximum thickness of 400–600 m. A lava sample from this unit 210 211 was dated at 17 ± 6 ka (Samaniego et al., 2016). An oblate, and esitic (61.3 wt.% SiO₂) lava dome lacking evidence for glacial erosion is located at the top of the northern cone 212 between 5,700 m asl and 6,000 m asl and is Ampato volcano's youngest feature. 213

214

Sabancaya volcano covers an area of 65–70 km² and comprises a volume of approximatly 215 6–10 km³ (Samaniego et al., 2016). Sabancaya is located northeast of the older Ampato 216 edifice and has two coalescing cones orientated in a SW-NE direction. Sabancaya's 217 eruptive chronology started with the older Basal edifice, which is represented by a 218 219 sequence of blocky, andesitic-dacitic (60.6-65.6 wt.% SiO₂) lava flows (SA-1) that spilled out onto the older rocks of the Ampato and Hualca Hualca edifices. These blocky 220 lava flows have individual thicknesses of 40-80 m, forming a 300-400 m thick lava pile 221 that extends as far as 8 km from the west to southeast of the summit (Fig. 2). A lava flow 222 from this stage was dated at 6.30 ± 0.31 ka by ³He surface-exposure dating (Samaniego 223 et al., 2016). We include in this stage the 400 m-high lava dome that forms the 224 southwestern part of Sabancaya's current summit (SA-2); as well as three andesitic (60.9-225

62.5 wt.% SiO₂) lava flow successions (SA-3) emplaced on the Sallalli plain (Fig. 2). 226 Bulmer et al. (1999) and Samaniego et al. (2016) linked this sequence to a satellite vent 227 located 4 km to the southwest of the active crater. Two samples from these blocky lava 228 flows were dated by Samaniego et al. (2016) at 6.65 ± 0.32 ka and 12.34 ± 0.55 ka by ³He 229 surface-exposure dating (Fig. 2). More recently, Bromley et al. (2019) measured helium 230 concentrations in two additional samples from Sabancaya layas, obtaining ages of $5.2 \pm$ 231 0.1 ka and 4.1 ± 0.1 ka (Fig. 2). In addition, a lava flow emplaced on the western flank of 232 the volcano covering a peat bog yielded an age of $5,440 \pm 40^{-14}$ C yr BP (Gerbe and 233 Thouret, 2004). Based on such geochronological information, Sabancaya's Basal edifice 234 was constructed during the Holocene. 235

Sabancaya's eruptive chronology continued during the Late Holocene with the 236 construction of a younger cone represented by a sequence of lava flows (SA-4) emplaced 237 discordantly upon the lavas of the previous stage. These lava flows reach 4–5 km from 238 the vent, have a thickness of 40-60 m and consist of andesites and dacites (61.7-65.7 239 wt.% SiO₂). This cone is covered by pyroclastic material and includes an active, semi-240 241 circular summit crater (Fig. 2) and a maximum diameter of 290 m. Explosive activity of Sabancaya continued until historic times. Two well-preserved ash-rich tephra-fall 242 deposits in the Sallalli peat bog southeast of Sabancaya were emplaced between 4.5 ka 243 244 and 3 ka (Samaniego et al., 2016). In the Quebrada Huaraya section, a 10–30 cm-thick coarse ash layer was found, where the underlying peat yielded an age of 265 ± 30^{14} C yr 245 BP. This age agrees with the 300 ± 50^{14} C yr BP date obtained by Juvigné et al. (2008) 246 and confirms the occurrence of explosive eruptions during the 17th or 18th century 247 (Travada and Córdova, 1752). 248

During the 20th century, eruptive activity resummed at Sabancaya, lasting from 1986 until 1998. In December 1986, Sabancaya experienced enhanced fumarolic activity

followed by an increase of explosive activity that culminated with an eruption (VEI 2) on 251 29 May 1990 (Gerbe and Thouret, 2004). Explosions generated columns of ash and gas 252 253 that rose 1–5 km above the crater during which ash was dispersed as far as 12 km from the summit. Then, recurrent at low to moderate explosive activity continued until 1998. 254 The bulk volume of the tephra emitted during the major phase of the eruption from May 255 to October 1990 was roughly estimated as 0.025 km³ (Thouret et al., 1994). In 2013, 256 Sabancaya experienced a significant increase in seismic activity and gas emissions that 257 258 eventually rose to 2,000 m above the summit. Subsequently, in November 2016, a new eruptive period began and is ongoing through the time of writing (May 2023). This 259 eruptive activity is characterised by vulcanian explosions associated with frequent gas 260 261 and ash emissions which in July 2017 formed eruption columns reaching up to 5,000 m above the summit. Associated with the 2016–2020 eruptive activity, we observe newly 262 emplaced lava domes inside the summit crater. 263

264

4. Sample collection and preparation, and analytical methods

4.1. Field sampling and sample preparation

Geological mapping, stratigraphic studies and sampling were conducted during several field campaigns between 2009 and 2020. We collected 138 samples that are representative of most volcanic units (Fig. 2).

270

271 4.2 Analytical methods

272 *4.2.1. Mineral analyses*

Thin sections of all samples were prepared for petrographic studies and electron microprobe analysis. The mineral analyses for 26 samples were obtained using a CAMECA SX-100 electron microprobe at the Laboratoire Magmas et Volcans (Université Clermont Auvergne, Clermont-Ferrand, France). Operating conditions for
mineral analyses were 15 keV accelerating voltage, 10 nA beam current and 10 s counting
time. The estimated error for a single analysis is about 1% when the element concentration
is higher than 10%, whereas for element concentrations lower than 10% uncertainty is 2–
5%. Composition data for phenocrysts from each volcanic unit are presented in
Supplementary Electronic Material (SEM 1).

- 282
- 283 4.2.2. Major and trace element whole-rock analyses

Major and trace element concentrations in 132 whole-rock samples were 284 determined at the Laboratoire Geosciences Océan, Université de Bretagne Occidentale 285 (Brest, France). Agate-ground powders were dissolved in HNO3 and HF and then 286 measured by ICP-AES (Inductively Coupled Plasma-Atomic Emission Spectroscopy), 287 following the procedure of Cotten et al. (1995). Relative standard deviations are 1% for 288 SiO_2 and <2% for the other major element oxides, except for low concentrations 289 (<0.50%), for which the absolute standard deviation is 0.01%. For trace elements, the 290 291 relative standard deviation is ca. 5%. Calibrations were performed using international standards JB2, BEN, ACE, WS-E, PM-S as well as specific reference samples. All 292 analyses were recalculated on an anhydrous basis with iron expressed as Fe₂O₃*. We add 293 294 to the database 6 major and trace element analyses from the 1990 eruptive products published by Gerbe and Thouret (2004). Representative whole-rock analyses are 295 presented in Table 1, while all whole-rock analyses are presented in SEM 2. 296

297

298 4.2.3. Sr, Nd, and Pb whole-rock analyses

Sr and Nd isotope analyses of 37 samples from Ampato and Sabancaya lavas were
 performed at the Laboratoire Magmas et Volcans (Clermont-Ferrand, France) on whole-

rock powders, which were dissolved using an HF/HNO₃/HClO₄ mixture. Sr and Nd were 301 separated by ion-exchange chromatography according to the procedures described in Pin 302 et al. (1994) and Pin and Santos-Zalduegui (1997). ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd isotopic 303 ratios were determined using either a VG Isomass 54E multicollector mass spectrometer 304 or a Finnigan TRITON. During the period of measurements, SRM-987 and AMES 305 gave ⁸⁷Sr/⁸⁶Sr=0.710239 \pm 0.00002 Rennes standards (2σ, n=4) 306 and $^{143}\text{Nd}/^{144}\text{Nd}=0.5119651 \pm 0.000015$ (2 σ , n=4). Six additional Sr/Nd isotopic ratios 307 published by Gerbe and Thouret (2004) and three published by Mamani et al. (2010) are 308 also included. Pb isotopic ratios were measured by MC-ICP-MS (Multicollector 309 310 Inductively Coupled Plasma Mass Spectrometer) at Laboratoire Magmas et Volcans 311 (Clermont-Ferrand, France) following the procedure described by Nauret et al. (2018). Pb isotope ratios are normalized to values of the NIST SRM 981 standard provided in 312 Galer and Abouchami (1998). Selected whole-rock major and trace elements, and Sr, Nd, 313 and Pb isotopic ratios are presented in Table 1 and all the data are in SEM 2. 314

315

316 5. Characterisation of Ampato-Sabancaya volcanic rocks

5.1. Petrography and mineral chemistry

Textures and mineral assemblages are similar throughout the ASCV rocks. The 318 319 lava and pyroclastic deposits of ASCV are often porphyritic with intersertal and/or vitreous groundmass (Fig. 3). Ampato eruptive products are dominated by andesitic 320 (~50%) and dacitic compositions (~46%), although some scarce (~4%) rhyolitic samples 321 were also reported (Table 2). The lavas contain up to 30 vol.% phenocrysts, which are 322 generally 0.2–3.0 mm and rarely up to 6.0 mm, and are variably vesicular (2–8 vol.%). 323 Less than 8% of the lavas are subaphyric to poorly porphyritic, especially the lavas of the 324 Ampato Basal edifice. The pyroclastic products contain between 10-30 vol.% 325

phenocrysts, which are generally 0.2–2.2 mm and rarely up to 4.0 mm, and are variably 326 vesicular (10-60 vol.%). Ampato andesites have a phenocryst assemblage of plagioclase 327 (Pl), clinopyroxene (Cpx), amphibole (Amp), biotite (Bt), and magnetite (Mag) together 328 with scarce orthopyroxene (Opx), and olivine (Ol). The Ampato dacites host phenocrysts 329 of Pl + Cpx + Bt + Amp + Mag and scarce Opx. The fine-grained groundmass of these 330 rocks consists of Pl + Cpx + Amp + Mag, and scarce colourless to brownish interstitial 331 glass. The rhyolites contain Pl + Bt + Mag and scarce alkali feldspar (Kfs) and quartz 332 (Qz). 333

Some dense juvenile blocks belonging to block-and-ash flow deposits from the Ampato Upper edifice have dark brown and light gray bands. The dark brown bands contain phenocrysts of plagioclase (20–25 vol.%), amphibole (5–10 vol.%), clinopyroxene (2–4 vol.%), and biotite (2–4 vol.%), included within a vesicular matrix. In contrast, the light gray bands contain less phenocrysts than the dark brown bands and have an assemblage of plagioclase (2–4 vol.%), biotite (2–4 vol.%), and clinopyroxene (1-2 vol.%) within a glassy matrix.

341 Sabancaya's eruptive products are andesitic (~62%) and dacitic (~38%) in composition (Table 2). The lavas contain up to 30 vol.% phenocrysts, which are generally 342 0.2–4.0 mm and rarely up to 7.0 mm. Samples are variably vesicular, with <8 vol.% for 343 344 lavas and 4-10 vol.% for pyroclastic products. All andesites and dacites (e.g., SA-1, SA-2, SA-3) have an assemblage of Pl, Amp, Bt, Cpx, and Mag together with scarce Opx, 345 and Ol. While such mineral phases are ubiquitous, their relative proportions are variable. 346 The fine-grained groundmass (<80 µm) consists of Pl, Amp, Cpx, Mag, and scarce 347 colourless, grey, or brownish interstitial glass. 348

The eruptive products emitted during the 1990–1998 eruption are andesites and dacites (60-64 wt.% SiO₂). According to Gerbe and Thouret (2004), all eruptive products are porphyritic with 20-25 vol.% phenocrysts. Some dense juvenile blocks have dark brown and light grey bands. The mineral assemblage consists of plagioclase (0.2–4 mm), amphibole (>0.2 mm), clinopyroxene, biotite, and Fe-Ti oxides. Eruptive products emitted during the 2017 CE eruptions are homogeneous, porphyritic andesites (60-61 wt.% SiO₂), with 40-50 vol.% phenocrysts. These andesites have a mineral assemblage consisting of plagioclase (20–25 vol.%), amphibole (4–6 vol.%), clinopyroxene (4–6 vol.%),), orthopiroxene (<1-2 vol. %), biotite (<1-2 vol. %) and Fe-Ti oxides.

358

359 5.1.1. Plagioclase

Plagioclase is the most abundant phenocryst phase in Ampato-Sabancaya rocks 360 361 and occurs as euhedral to subhedral phenocrysts (20-40 vol.%) as well as microlites (SEM 1). Based on textural and chemical characteristics, we identify two different plagioclase 362 populations: (1) euhedral, non-altered phenocrysts with normal, oscillatory and/or reverse 363 zoning patterns; and (2) sieve-cored or sieve-ringed phenocrysts with frequent dissolution 364 zones and overgrowth rims displaying strong reverse zoning. In samples from Ampato 365 366 Basal edifice, the anorthite content in plagioclase ranges from labradorite to oligoclase (An₂₄₋₇₂, Table 3, SEM 3). In Ampato Upper andesites the plagioclase is bytownite, 367 labradorite, and esine, and oligoclase (An₂₈₋₇₅), while in Ampato Upper dacites (including 368 those of the Corinta unit) the plagioclase is labradorite, and esine, and oligoclase (An₂₈₋ 369 57). In both eruptive stages, normal zoning is frequent while reverse zoning is scarce. In 370 Sabancaya andesites and dacites the anorthite content of plagioclase includes labradorite, 371 andesine, and oligoclase (An₂₇₋₆₃). Normal zoning is frequent in some phenocrysts while 372 reverse zoning is scarce. In the products of the 1990 activity, the composition varies 373 374 from oligoclase to labradorite (An₂₆₋₆₂), of which andesine is predominant (Gerbe and Thouret, 2004). The andesites contain a mixed population of plagioclase 375

phenocrysts: Ca-rich clear plagioclase (An₄₀₋₆₀), Na-rich clear plagioclase (An₂₅₋₃₅),
and inversely zoned "dusty rimmed" plagioclase with a sodic core (An₂₅₋₄₀)
surrounded by a Ca-rich overgrowth rim (An₄₅₋₆₅) (Gerbe and Thouret, 2004). In the
juvenile blocks of the 2017 CE eruptions the composition varies from andesine to
labradorite (An₃₆₋₅₅).

381

382 5.1.2. Clinopyroxene

383 Clinopyroxene occurs as euhedral to subhedral phenocrysts (<8 vol.%; up to 1 mm in size) as well as microlites in the andesites and dacites (Table 2). In Ampato 384 andesites and dacites (from both Basal and Upper edifices) clinopyroxenes have a 385 386 restricted compositional range from diopside to magnesian augite (En39-46-Fs12-19-Wo40-47, following Morimoto et al. 1988) with Mg# [where Mg# = $100*Mg/(Mg + Fe^T)$ in 387 mol.%, and Fe^{T} is total iron as Fe^{2+} from 74–84 (Table 3, SEM 1, SEM 4). They generally 388 389 are normally zoned (e.g., SA-1102: Mg# 80-76), but rare reverse zoning also exists (e.g., SA-1137: Mg# 72-76). In Sabancaya andesites and dacites, clinopyroxenes also have a 390 homogeneous compositional range from diopside to magnesian augite (En₃₈₋₄₈-Fs₁₁₋₁₇-391 W040-46) with Mg# 72-85 (SEM 1 and SEM 4). They generally have normal (e.g., SA-392 0907: Mg#79-76) and reverse zoning patterns (e.g., SA-1152: Mg#73-79). The rocks of 393 394 the 1990-1998 eruption contain clinopyroxenes, essentially augites (En40-46-Fs15-16-W040-46), similar to the rocks from the 2017 CE eruption (En₄₁₋₄₃-Fs₁₅₋₁₆-Wo₄₀₋₄₃) with Mg# 395 ranging from 77 to 79. Additionally, some Sabancaya and Ampato Upper edifice (AMII-396 397 3) clinopyroxene are Mg- and Cr-rich (Mg# 72-78, up to 0.1 wt % Cr₂O₃) (SEM 4). These high Mg# and Cr₂O₃ contents suggest that these minerals crystallized from more primitive 398 399 magmas.

400

401 *5.1.3. Orthopyroxene*

Euhedral and subhedral orthopyroxene are present as phenocrysts and microlites 402 403 (<8 vol. %; up to 1 mm in size) in most andesites and some dacites (Table 3). In Ampato andesites and dacites, orthopyroxene has a compositional range from En_{62-76} (Table 3, 404 SEM 1 and SEM 4). While in andesites from Sabancaya they have a compositional range 405 from En₄₁₋₇₆. The orthopyroxene of the Ampato andesites are sligtly less magnesian 406 compared to Sabancaya orthopyroxene. In Ampato and Sabancaya rocks, orthopyroxene 407 408 has slight normal zoning patterns (e.g., Ampato andesite SA-1033C: Mg# 75-72; Sabancaya andesite SA-0907: Mg# 78–76) and scarce reverse zoning (e.g., Ampato dacite 409 SA-0930: Mg# 72–78; Sabancaya andesite SA-0906: Mg# 66–78). The orthopyroxene 410 411 from the 2017 CE eruptions have homogeneous compositions (En₇₁₋₇₂). Orthopyroxene is absent in the rhyolites. 412

413

414 *5.1.4. Amphibole*

Amphibole phenocrysts are present in different modal proportions (up to 10 415 416 vol.%; up to 4 mm in size) in andesite and dacite lavas and pyroclastic products from Ampato and Sabancaya (Table 3). They are an accessory phase (~1 vol.%) in some 417 Ampato Basal andesites, with subhedral forms and frequent, thin opaque (black) reaction 418 419 rims. In contrast, amphibole phenocrysts in the Ampato Upper and Sabancaya andesites and dacites are much more abundant (2-10 vol.%), are euhedral and subhedral, and 420 display scarse disequilibrium features. Indeed, thin opaque (black) reaction rims are 421 sometimes observed, and very scarsely some amphiboles are completly replaced 422 (pseudomorphs) by Fe-Ti oxides and pyroxene aggregates (e.g., SA-0918, 0911). 423 Amphibole phenocrysts in Ampato Basal rocks have magnesio-hastingsite compositions 424 while those of Ampato Upper and Sabancaya are edenite, magnesio-hastingsite, 425

magnesio-hornblende, and tschermakite (SEM 3) (Leake et al., 1997). Values of Mg# for 426 amphibole in Ampato andesites and dacites vary from 70-83. There is minimal variation 427 of Mg# among the different eruptive stages of Ampato, although normal (e.g., andesite 428 SA-1155: Mg# 74-71) and reverse zoning are observed (e.g., dacite SA-1127C: Mg# 74-429 78). The amphiboles in Sabancaya andesites and dacites have Mg# values that vary from 430 70-89, with mainly normal (e.g., andesite SA-0907: Mg# 85-79) and reverse zoning 431 patterns (e.g., dacite SA-1015: Mg# 71-73). The rocks from the 2017 CE eruptions 432 433 contain amphiboles with magnesium-hornblende and magnesium-hastingsite compositions (Mg# 72-77). 434

435

436 *5.1.5. Biotite*

Biotite crystals occur in andesites, dacites, and rhyolites from Ampato and 437 Sabancaya (SEM 1). Biotite (up to 6 vol.%, up to 3 mm in size) has euhedral and subhedral 438 habits. Some phenocrysts have inclusions of plagioclase, clinopyroxene, and Fe-Ti oxide 439 microlites. In some lavas, biotite crystals are armored by opaque minerals and plagioclase 440 441 microlites (e.g., SA-0905; SA-0919). Ampato biotite is characterized by high proportions of $Fe^{+2}/(Fe^{+2}+Mg)$ (0.34-0.61) while Sabancaya biotite have narrow $Fe^{+2}/(Fe^{+2}+Mg)$ 442 values (0.40-0.44). All biotite crystals display high Al₂O₃ (11.4-29.5 wt.%) (Table 2, 443 444 SEM 1), and TiO₂ (3.8-5.9 wt.%) concentrations, whereas Mg# is relatively low (49-66). 445

446 *5.1.6. Olivine*

Olivine appears only as an accessory phase (<2 vol.%) in mafic andesites of Ampato Basal stage (Table 2 and 3) and are mostly subhedral and anhedral phenocrysts (<0.8 mm). The olivines have low magnesium content with forsterite (Fo) contents that vary in the range Fo_{68–77}. The phenocrysts have subtle normal zoning (e.g., SA-1102: Fo₇₃₋₇₂). In Sabancaya, olivine is scarce and appears in some andesitic lavas with slightly higher forsterite contents in the range Fo₈₀₋₈₂. In this group, weak normal zoning is observed (e.g., SA-0906: Fo₈₀₋₈₂).

454

455 5.1.7. Fe-Ti oxides

Fe-Ti oxides (with sizes >40 μ m) are present in the groundmass or as inclusions within pyroxenes, biotite, amphibole, and some olivine phenocrysts. All studied samples contain titano-magnetite, while some high-silica andesites and dacites of Sabancaya and Ampato also containt scarce ilmenite (SEM 1).

460

461 *5.1.8. Accessory minerals*

462 Quartz appears as anhedral microphenocrysts in the most silica-rich samples (SiO₂ 463 >70 wt.%) or as small grains in the groundmass of some dacites. Alkaline feldspars appear 464 as phenocrysts of sanidine (Or₇₀₋₇₁, Table 3, SEM 3) in some rhyolites. Apatite is found 465 as inclusions in almost all mineral phases (amphibole, biotite, pyroxenes, and 466 plagioclase).

467

468 **5.2. Main geochemical characteristics**

469 5.2.1. Major and trace elements

All analysed samples plot in the high-K calc-alkaline field of Peccerillo and Taylor (1976) (Fig. 4). The rocks of Ampato have a wide compositional range between basic andesites to dacites (56.7–69.33 wt.% SiO₂; 2.0–4.9 wt.% K₂O) while those of Sabancaya range between andesites and dacites (60.0–65.7 wt.% SiO₂; 2.7–3.6 wt.% K₂O). In this analysis, we also include the rhyolitic deposits that crop out to the west of Ampato-Sabancaya. The eruptive products of the 1990-1998 activity are andesites and dacites (60.6–63.8 wt.% SiO₂), while the eruptive products of the 2017 activity are mainly
andesitic (58.2–61.2 wt.% SiO₂).

478 In general, the ASCV samples display a single magmatic trend, but a more detailed analysis reveals that four different groups are present. (1) the first group, 479 composed mainly of andesites (56.7–59.8 wt.% SiO₂), corresponds to lavas from the 480 early andesitic stage of the Ampato Basal edifice, as well as to the scoriaceous tephra-481 fall and pyroclastic-flow deposits of Ampato Upper edifice (Fig. 4). These samples 482 are porphyritic lavas and tephras with plagioclase, ortho- and clinopyroxene, and Fe-483 Ti oxides. (2) The second group corresponds to andesitic and dacitic compositions 484 (60.0-67.3 wt.% SiO₂) from the Moldepampa stage, Ampato Upper edifice, and 485 486 Sabancaya edifice. All these samples are porphyritic with phenocrysts of plagioclase, amphibole, biotite, ortho- and clinopyroxene, and Fe-Ti oxides. (3) The third group 487 corresponds to dacitic compositions (65.0-69.3 wt.% SiO₂) associated with the Corinta 488 Plinian tephra-fall and pyroclastic-flow deposits of the Ampato Upper edifice (Fig. 4). (4) 489 A final group consists of the rhyolites (74.2–76.9 wt.% SiO₂) that correspond to tephra-490 491 fall deposits ascribed by Samaniego et al. (2016) to the Ampato Basal edifice.

492 A compositional evolution over time is not apparent. When plotted in Harker diagrams (Fig. 4), the andesites and dacites do not align along a single trend, and are 493 494 separated from the rhyolitic eruptive products by a compositional gap between 69 wt.% SiO₂ and 74 wt.% SiO₂. In binary diagrams (Fig. 4), all major oxides (except K₂O) are 495 negatively correlated to SiO₂, whereas trace elements show positive correlations with 496 silica, especially for the Large-Ion Lithophile Elements (LILE, e.g., Rb, Th, Ba). In these 497 diagrams, compared to dacites of group 2, group 3 dacites have slightly elevated 498 concentrations in some major and trace elements (e.g., K₂O, Al₂O₃, Rb, Zr, Sm, La, Yb), 499 and lower concentrations for other elements (e.g., MgO, CaO, Sr, Ni, Cr). The Rare Earth 500

Elements (REE) have a noteworthy pattern because the Middle REE (MREE, e.g., Sm) and Heavy REE (HREE, e.g., Dy, Yb) are reversely correlated with silica. In contrast, High Field Strength Elements (HFSE, e.g., Nb) are positively correlated, while Light REE (LREE, e.g., La, Ce) have a subtle positive correlation. Additionally, Y, Zr, Sr, and the transition metals (e.g., Sc, V, Cr, Ni) are negatively correlated with silica. Lastly, the rhyolites plot along the trend defined by group 2, except for LREE (e.g., La, Ce), LILE (e.g., Th), and HFSE (e.g., Nb).

Multi-element diagrams normalised to primitive mantle (Sun and McDonough, 1989) suggest that Ampato-Sabancaya lavas are typical of continental arc magmas (Fig. 5). Compared to the primitive mantle, these samples are enriched (~100 times) in LILE (e.g., Ba, Rb, Th, K) and LREE (e.g., La, Ce). The HFSE (e.g., Nb and Zr) show a marked negative anomaly as well as P and Ti. The rhyolites have more prominent P and Ti anomalies than group 3 dacites, which are in turn more prominent than group 2 dacites.

The REE patterns normalised to chondrites (Sun and McDonough, 1989) for 514 ASCV rocks are almost parallel and have large LREE enrichments (77.5<La_N<247.5) and 515 516 HREE depletions (4.7<Yb_N<10.8). In contrast, group 4 rhyolites have universally lower 517 REE contents with respect to groups 1 and 2 rocks, while group 3 dacites have higher values of MREE and HREE compared to groups 1, 2, and 4. The REE patterns for most 518 519 andesites and dacites are also characterized by a relatively weak Eu anomaly (Fig. 5). Indeed, a detailed analysis of the behavior of HREE and other trace elements shows that 520 the rhyolite samples do not follow the same geochemical trend, precluding a single 521 differentiation process linking Ampato-Sabancaya andesites and dacites with the 522 rhyolites (even if we include allanite and/or monazite as accessory minerals in the 523 cumulate). 524

525

526 5.2.2. Isotopic ratios

The 87 Sr/ 86 Sr ratios of the Ampato-Sabancaya andesite and dacite lavas range from 0.70633–0.70765, while the 143 Nd/ 144 Nd ratios range from 0.51229–0.51243 (Table 1, Fig. 6). The 87 Sr/ 86 Sr ratios of the rhyolites range from 0.7072–0.7088, while the 143 Nd/ 144 Nd ratios range from 0.51211–0.51230 (Fig. 6). Excluding these rhyolitic compositions, the most radiogenic Sr values (and conversely the most unradiogenic Nd values) are displayed by group 3 dacites from the Ampato Upper edifice (Fig. 6b).

In the ⁸⁷Sr/⁸⁶Sr versus ¹⁴³Nd/¹⁴⁴Nd diagram (Fig. 6a), the Ampato-Sabancaya 533 samples display a negative correlation and plot far from the mantle domain represented 534 by the MORB field. Sr and Nd isotopic data have broadly homogeneous values at the 535 536 scale of the CVZ (Davidson et al., 1991; Fig. 6a). Such characteristics suggest that ASCV magmas are contaminated by the continental crust, an interpretation corroborated by a 537 positive correlation observed in the ⁸⁷Sr/⁸⁶Sr versus SiO₂ diagram (Fig. 6b). This 538 relationship between SiO₂ content (or any other differentiation index) and the isotopic 539 composition of Ampato-Sabancaya magmas provides strong evidence for contamination 540 541 by continental crust, possibly through an AFC process or magma mixing involving a 542 crustally-derived end-member.

The ²⁰⁶Pb/²⁰⁴Pb ratios of the andesites and dacites eruptive products range from 543 18.172 to 18.489, the 207 Pb/ 204 Pb ratios range from 15.612 to 15.625, and the 208 Pb/ 204 Pb 544 ratios are from 38.546 to 38.715 (Table 1). In contrats, the rhyolites display very 545 heterogeneous lead isotopic values (206Pb/204Pb: 17.817-18.214; 207Pb/204Pb: 15.599-546 15.614; ²⁰⁸Pb/²⁰⁴Pb: 38.469–38.715). We stress that least differentiated sample (SA-547 1033E, Fig. 7) display the highest Pb istopic ratios. The Ampato-Sabancaya samples plot 548 in the typical fields for the Andean Central Volcanic Zone field (Mamani et al., 2010), 549 southern part of Arequipa segment, and northern part of the Toquepala segment of the Peruvian 550

⁵⁵¹ Coastal batholith (Mukasa, 1986) (Figs. 7a, b). In some diagrams (Fig. 7), the samples show a well-defined negative correlation pointing towards the Charcani gneiss field from the Arequipa Massif (Figs. 7c, d). Similar to the Sr isotope data, group 3 and group 2 dacites have homogeneous Pb isotope compositions, with lower ²⁰⁶Pb/²⁰⁴Pb for a given ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁸Pb/²⁰⁴Pb value compared to andesites. A low ²⁰⁶Pb/²⁰⁴Pb reflects the influence of Precambrian-age crust such as the Arequipa massif of southern Peru (Barreiro and Clark, 1984; James, 1982; Mamani et al., 2010).

The lead isotopic data (Figs. 7c, d) shows that most samples plot in a roughly 558 linear distribution. However, dacites from group 3 and some samples of Ampato Upper 559 edifice (group 2) have systematically low ²⁰⁶Pb/²⁰⁴Pb and high ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁸Pb/²⁰⁴Pb 560 561 values. This distribution cannot be explained by a single assimilation-fractional crystallization or binary mixing process, suggesting that at least three end-members must 562 be involved. We consider this hypothesis in the following sections and propose a model 563 that accounts for magma mixing, fractional crystallization, and different crustal 564 contaminants. 565

566

567 5.2.3. Temporal change in magma composition

Figure 8 plots selected major and trace element compositions and ratios, as well 568 as isotopic ratios against stratigraphic position of the erupted products established 569 according to geological and geochronological information (Rivera et al., 2016; 570 Samaniego et al., 2016). During the growth of Ampato Basal edifice, and esitic and dacitic 571 (57-65 wt.% SiO₂) magmas were emitted. Later, during construction of the Ampato 572 Upper edifice, volcanic products with a wide geochemical variability from andesites to 573 dacites (57-69 wt.% SiO₂) were erupted. In addition, the groups 2 and 3 dacites were 574 emitted at roughly the same time (i.e. Ampato Upper edifice). During Sabancaya's 575

evolution, the SiO₂ content varies slightly between andesites and dacites (60–66 wt.% 576 SiO₂), but is relatively constant and similar to that of group 2 andesites and dacites of 577 Ampato Upper edifice. In recent times, the geochemical composition of erupted magmas 578 is roughly andesitic (57-63 wt.% SiO₂). Trace element ratios (e.g., Sr/Y) as well as 579 ⁸⁷Sr/⁸⁶Sr, ²⁰⁶Pb/²⁰⁴Pb, ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁸Pb/²⁰⁴Pb ratios (Fig. 8) also have a wide 580 compositional variation throughout the Ampato Basal edifice and predominantly 581 homogeneous compositions throughout Sabancaya. It is worth noting that group 3 dacites 582 have low Sr/Y values, but high ⁸⁷Sr/⁸⁶Sr ratios, a pattern that contrasts with group 2 583 dacites (high Sr/Y and high ⁸⁷Sr/⁸⁶Sr ratios). Through its evolution, most differentiated 584 products (mostly dacites) were erupted between 40 ka and 20 ka, however, the 585 586 geochemical and isotopic signatures of these dacites (groups 2 and 3) suggest that the crustal process responsible for their petrogenesis are not the same. Lastly, we would stress 587 that rhyolites display wide Pb isotopes values (cf. ²⁰⁸Pb/²⁰⁴Pb), therefore based on this 588 data and their trace elements behaviour (see above), we conclude that rhyolites (group 4) 589 do not belong to the Ampato-Sabancaya magmatic series. 590

591

592 6. Discussion

593 **6.1. The sources of Ampato-Sabancaya magmas**

Previous studies suggest that the primitive magmas for volcanoes in Southern Peru essentially result from partial melting of mantle peridotite that was previously metasomatised by fluids released during dehydration of the subducting slab (Thorpe et al., 1984; Vatin-Pérignon et al., 1992; Thouret et al., 2005; Delacour et al., 2007; Mamani et al., 2010; Rivera et al., 2017; Huang et al., 2017; Samaniego et al., 2020). In the case of the ASCV magmas, their chemical and isotopic signatures point out to intermediate to differentiated compositions, precluding a purely mantle origin.

The source and evolution of magmas feeding the composite CVZ volcanoes has 601 been extensively investigated wether on a regional (James, 1982; Barreiro and Clark, 1984; 602 603 Hildreth and Moorbath, 1988; Davidson et al., 1991; Mamani et al., 2010; Blum-Oeste and Worner, 2016; Burns and de Silva, 2023) or single edifice scales (Davidson et al., 1990; 604 Feeley and Sharp, 1995; Delacour et al., 2007; Sorensen and Holm, 2008; Thouret et al., 605 2005; Rivera et al., 2017; Samaniego et al., 2020). Because shallow differentiation 606 processes affected magma composition, its mantle source is difficult to assess. For this 607 reason, geochemists are interested for the scarce primitive compositions erupted in this arc 608 segment. The Andahua-Huambo eruptive products display similar petrographic and 609 geochemical characteristics than those of the other composite volcanoes, however they 610 611 also display some key differences, namely the presence of olivine-rich, basaltic andesitic compositions ranking among the most primitive lavas erupted at the CVZ (Delacour et al., 612 2007). Among these characteristics, we can mention low silica contents (as low as 52 wt.% 613 SiO₂), relatively high MgO and Mg# values (2.02–7.33 wt.% MgO; Mg# 39.31–61.55), 614 and unradiogenic isotopic ratios (0.7059-0.7069 ⁸⁷Sr/⁸⁶Sr; 0.5123-05125 ¹⁴³Nd/¹⁴⁴Nd; 615 18.298–18.629²⁰⁶Pb/²⁰⁴Pb; 15.558–15.601²⁰⁷Pb/²⁰⁴Pb; 35.546–38.643²⁰⁸Pb/²⁰⁴Pb). Thus, 616 617 the Andahua-Huambo lavas represent a base-line magma composition in Southern Peru and provide a window to unravel the deep crustal processes active at the CVZ. 618

Petrological characteristics of the Andahua-Huambo magmas suggest that they evolved at deep reservoirs, being slightly modified at shallow levels in the crust. Indeed, the low HREE and Y contents, and high La/Yb and Sr/Y ratios, and the Sr, Nd-, Pb-, and O-isotope compositions of Andahua-Huambo lavas reveal that these magmas evolved at high pressure in the so-called MASH zone, wheater by garnet-dominated AFC processes or lower crust partial melting leaving a garnet-bearing residue (Delacour et al., 2007; Sorensen and Holm, 2008; Huang et al., 2017). 626 In order to identified the arc magma sources of this part of the Andes, we followed the systematics proposed by Blum-Oeste and Wörner (2016), which suggest that CVZ 627 628 magmas resulted from a mixture of a mantle-derived basaltic andesite (BA); an enriched basalt (EB); a crust-derived rhyodacite (RD) (Fig. 9). In a Sr vs. SiO₂ plot most ASCV 629 630 compositions (at least the most primitive ones) fall inside the triangle formed by the previous end-members, and seems to define two different trends, the first one composed 631 by the andesites and dacites of the groups 1 and 2; and the second defined by the group 3 632 dacites. It is worth to note that SA 1033E sample, that represent the local mafic end-633 member for group 1 and group 2 fall relatively close to the mixing line formed between 634 the two primitive end-members (BA and EB), whereas the intermediate and silica-rich 635 compositions of groups 1 and 2 point to the high-silica end-member (RD). In contrats, the 636 the group 3 dacites plot outside the previously defined triangle. In this diagram, Andahua-637 Huambo compositions define a trend with a break-in-slope around 57 wt.% SiO₂. The 638 andesitic and dacitic compositions tend to merge the ASCV trend, whereas the low-silica 639 compositions fall along the BA-EB side, confirming the fact that primitive magmas in 640 641 this part of the arc are not homogeneous. Based on this analysis, we propose that parental 642 magmas for the group 1 and 2 should be different than that of the group 3.

643

644 **<u>6.2. Intracrustal processes</u>**

Ampato-Sabancaya magmas resulted from extensive crustal processing that include fractional crystallization, crustal assimilation, and magma mixing. We discuss the mineralogical and geochemical evidence for each of these processes.

648

649 6.2.1. Fractional crystallization

Several mineralogical and geochemical characteristics indicate that fractional 650 crystallization (FC) played an important role during the evolution of Ampato-Sabancaya 651 652 magmas. Among these characteristics are: (a) the presence of zoned plagioclase, clinopyroxene, and olivine phenocrysts; (b) the modal compositions of the main minerals 653 654 that vary with magmatic differentiation; (c) the well-correlated trends between some incompatible elements (e.g., Rb versus Th, Fig. 10a); and (d) the depletion in compatible 655 elements (e.g., Ni, Cr, Sr, Yb) along differentiation trends (Fig. 4, 10b). Trace element 656 variations clearly indicate mineral fractionation, such as decreases in Ni and Cr with 657 increasing silica contents which suggest olivine and clinopyroxene fractionation. 658 Depletion in MREE and HREE usually indicate amphibole and/or garnet crystallization, 659 whereas the negative trend observed in the MREE/HREE (e.g., Dy/Yb) vs. SiO₂ diagram 660 clearly suggests a leading role for amphibole fractionation (Fig. 11a). The decrease of Sr 661 suggests plagioclase fractionation (Fig. 4), a process that is corroborated by the relatively 662 weak negative Eu anomaly observed in most ASCV samples (Fig. 5). 663

To test our hypothesis that fractional crystallization occurred, we perform a two-664 665 step geochemical modelling procedure. First, major element mass-balance calculations (Störmer and Nicholls, 1978) between mafic and felsic end-members of the groups 1 and 666 2 (SA-1033E and SA-1169A, respectively) allow us to estimate the modal composition 667 of the cumulate (64-65% Pl + 18-23% Amp + 5-7 Bt + 2-4% Cpx + 5-6% Ti-Mag), as 668 well as the degree of crystallisation (72%) required to evolve from a basaltic andesite to 669 a dacite magma. It is noteworthy that the modal composition of the cumulate estimated 670 from such calculations is similar to the observed mineral assemblage in ASCV eruptive 671 products. Second, the calculated values are entered into the trace-element modelling 672 equations of Rayleigh (1896) (details on mathematical procedures are given in Janousek 673 et al., 2015). For the trace element modelling, we used the partition coefficients for 674

siliceous liquids of Martin (1987), Rollinson (1993), and Bachmann et al. (2005). We 675 would stress that the geochemical modelling approch is challenging for highly porphyritic 676 677 rocks (up to 30-40 vol.% crystals), which cannot be considered as true magmatic liquids following a liquid-line-of-descent. In addition, the geochemical dispersion observed in 678 some diagrams such as Rb versus Ni (Fig. 10b) suggests that fractional crystallization 679 alone cannot explain the observed geochemical diversity, indicating a more complex 680 scenario. For example, in this geochemical space, the olivine-clinopyroxene-dominated 681 682 fractional crystallization trend produces a noticeable decrease in Ni contents whereas Rb should be slightly increased. In addition, during fractional crystallization the ratio 683 between two incompatible elements will not change drastically and samples related 684 through fractional crystallization should define an approximately horizontal line if plotted 685 against a fractionation index. This is not the case, as demonstrated by the K/Rb ratio 686 which decreases with increasing Rb concentration (Fig. 11b). Thus, despite mineralogical 687 and geochemical data suggesting an important role of fractional crystallization of a 688 cumulate composed of plagioclase, pyroxenes, amphibole, and Fe-Ti oxides, other 689 690 processes such as magma mixing and crustal assimilation must also be involved.

691

692 6.2.2. Assimilation-fractional crystallization (AFC)

The ASCV data supports the hypothesis that crustal contamination played a key role in andesite and dacite magma genesis. The curved trend observed in K/Rb *vs.* Rb (Fig. 11b) demonstrates that Rb is more incompatible than K, a trend commonly present in other CVZ magmatic series and associated with AFC process (Davidson et al., 1990). In addition, ⁸⁷Sr/⁸⁶Sr positively correlates to SiO₂ content (Fig. 6b) while ¹⁴³Nd/¹⁴⁴Nd is negatively correlated to SiO₂ content in Ampato-Sabancaya samples (not shown). Such relationships are typical of crustal contamination (Leeman and Hawkesworth, 1986;

DePaolo, 1981) and are widely documented in lavas throughout the CVZ (e.g., Thorpe et 700 al., 1984; Hildreth and Moorbath, 1988; Davidson et al., 1991; Gerbe and Thouret, 2004; 701 Delacour et al., 2007; Sørensen and Holm, 2008; Mamani et al., 2010; Godoy et al., 2014; 702 Rivera et al., 2017). Additionally, Pb isotope ratios for Ampato-Sabancaya eruptive 703 15.61<²⁰⁷Pb/²⁰⁴Pb<15.63, products (18.17<²⁰⁶Pb/²⁰⁴Pb<18.49; 704 and 38.55<²⁰⁸Pb/²⁰⁴Pb<38.72) point to those reported for the regional metamorphic basement 705 (Barreiro and Clark, 1984; Mamani et al., 2008; Figs. 7a and b), providing evidence that 706 707 the Ampato-Sabancaya magmas assimilated significant amounts of Arequipa Massif basement during their ascent. 708

Consequently, to account for isotopic and trace element constraints, we test 709 710 alternative models combining fractional crystallization with the assimilation of wall-711 rocks surrounding the magma reservoirs (AFC, DePaolo, 1981) (curve 1, Fig. 12). The 712 amount of assimilated material correlates to the quantity of magma that has crystallized through ascent and cooling. For AFC modelling, we use the same parameters as the FC 713 714 model, varying fractionation/assimilation ratios (r = 0.2), and the Precambrian Charcani 715 gneiss to represent the local upper continental crust composition (Boily et al., 1989; Sorensen and Holm, 2008; Rivera et al., 2017; Samaniego et al., 2020). The modelling 716 results for our AFC model are shown in Fig. 12. Using these parameters, we can 717 718 reproduce the geochemical diversity of andesites and dacites of groups 1 and 2. We stress that group 3 dacites cannot be modeled because, as showed in a previous section (see Fig. 719 9), the parental magmas of these dacites are different than that of the other ASCV 720 721 magmas.

722

723 *6.2.3 Magma mixing*

A magma mixing process is also suggested by the frequent disequilibrium textures 724 and chemical zoning patterns observed in ASCV rocks. For example, rocks emitted in the 725 1990-1998 Sabancaya eruptions frequently have disequilibrium textures (e.g., hybrid 726 andesites with a mixed population of plagioclase phenocrysts). Gerbe and Thouret (2004) 727 interpreted such features as evidence of mixing between andesitic and dacitic end-728 members during repeated injections of mafic magmas into the base of a ~6 km-deep 729 reservoir. In general, we observe: (a) reversely zoned plagioclase phenocrysts with 730 731 "wavy" dissolution surfaces between the core and rim, and Ca-rich overgrowth rims; (b) clinopyroxene, orthopyroxene, and amphibole phenocrysts have reverse zoning, 732 particularly in the outermost rims; (c) high Mg# and Cr₂O₃ contents in some 733 734 clinopyroxene phenocrysts suggest that these minerals crystallized from more primitive magmas. (d) banding textures observed at in some units of Ampato (AM-II5) and 735 Sabancaya, indicating that magma mixing and mingling must be taken into account when 736 interpreting the diversity of Ampato-Sabancaya magmas. 737

A magma mixing scenario is additionally suggested by the positive and negative 738 739 correlations of some trace elements against silica (Fig. 4), linear correlations among 740 incompatible trace elements, hyperbola-like trends in diagrams of incompatible trace element ratios (Clynne, 1999), and the distribution of compatible versus incompatible 741 742 elements (e.g., Ni vs. Rb diagram, Fig. 9b). To identify the main process responsible for the geochemical diversity recorded by ASCV magmas, we follow the trace element 743 systematics of Langmuir et al. (1978) and Schiano et al. (2010) which enable us to 744 distinguish between partial melting, fractional crystallization, and mixing processes. 745 746 Plotting Rb, an incompatible element, and V, a compatible element, in a Rb/V versus 1/V diagram, yields a a linear trend for most samples (Fig. 13) that suggests a binary mixing 747 process between a mafic mantle-derived end-member and a silica-rich end-member. 748

To test the magma mixing hypothesis in the ASCV series, we apply a trace 749 element mass-balance mixing model with mafic and siliceous end-members using the 750 equations of Langmuir et al. (1978). This model accurately describes the geochemical 751 diversity of both magmatic series (curve 2, Fig. 13), and allows us to constrain both basic 752 and silicic end-members. The basic end-member is represented by the most magnesian 753 (group 1), mantle-derived magmas of the Ampato edifice (e.g., SA-1033E). This mafic 754 end-member is depleted in incompatible trace elements, such as LILE and LREE, and has 755 756 low values for trace element ratios (e.g., Th/La, La/Yb). In contrast, this end-member has high concentrations of most compatible elements such as HREE and the transition metals. 757 The silicic end-member is represented by group 2 dacites (*i.e.*, SA-0914), which are 758 759 characterized by enrichment in most incompatible elements, as well as low concentrations of compatible elements. Additionally, in the geochemical spaces represented in Fig. 13, 760 an extrapolation of the mixing model beyond the silicic end-member potentially leads to 761 group 3 dacite compositions. We stress, however, that trace elements systematics (Fig. 4) 762 demonstrate that group 2 dacites are geochemically different from group 3 dacites, 763 764 implying that two different "recipes" are needed to produce these distinct silica-rich 765 magmas.

766

767 6.3. The origin of Ampato dacites: different sources or different levels of 768 differentiation?

As mentioned, Ampato dacites display two contrasting geochemical signatures. Group 2 dacites are characterized by depletion in HREE and Y, which yield high Sr/Y (50.91–60.50) and Dy/Yb (2.14–2.61) ratios (Fig. 11a). Additionally, they have high 87 Sr/⁸⁶Sr (0.7068–0.7070), 206 Pb/²⁰⁴Pb (18.2098–18.2537), 207 Pb/²⁰⁴Pb (15.6136– 15.6159), and 208 Pb/²⁰⁴Pb (38.5464–38.5791) ratios. In contrast, group 3 dacites have particular geochemical and isotopic feature that differ from most Ampato-Sabancaya
eruptive products. These dacites show high concentrations in HREE and Y compared to
andesites and dacites from group 2, and as a result these dacites also yield very low Dy/Yb
ratios (1.76–2.14, Fig.11a). In addition, group 3 dacites yield very high Sr isotopic ratios
(0.7074–0.7075).

The relatively low Yb and Y contents of most Ampato-Sabancaya andesites and dacites might have been acquired during the first stage of evolution in the lower crust through AFC processes involving garnet and/or amphibole from primitive mantle-derived parental magma (e.g., Davidson et al., 1990, 1991; Kay, 2002; Haschke et al., 2006; Sørensen and Holm, 2008; Mamani et al., 2010). Then, in a second step, amphiboledominated, upper crustal AFC processes would be responsible for the formation of group 2 andesites and dacites.

In contrast, the low Sr/Y and Dy/Yb ratios of group 3 dacites clearly indicate a 786 magmatic evolution under conditions where garnet and/or amphibole are not stable 787 mineralogical phases (Taylor and McLennan, 1988; Alonso-Pérez et al., 2009). However, 788 789 given that Sr and Pb isotopic ratios are high for both dacite groups, significant crustal 790 contamination occurs. We propose that group 3 dacites formed at upper crustal levels, following and AFC process in which amphibole do not play a leading role. Thus, two 791 792 contrasting processes are responsible for the origins of both dacite groups. These processes differ on the depth at which crustal contaminations occurs, with deeper levels 793 for group 2 and shallow levels for group 3 (Fig. 14). This difference suggests that a 794 complex magma plumbing system exists below the ASVC and implies that the 795 796 voluminous explosive eruptions that produced the Corinta Plinian tephra-fall deposits of the group 3 dacites required the development of large upper crustal reservoirs. In addition, 797 as mentioned before, the parental magmas of the group 3 dacites seems to be different of 798

that feeding the main ASCV plumbing system, which implies that these magmas by passed the deep crustal source and then they did not acquire the classical HREE-depleted garnet-signature of the other ASCV magmas.

802

803 7. Conclusions

During about the last 500 ky, Ampato-Sabancaya eruptive products have 804 geochemical and isotopical variations that define three different geochemical groups: (1) 805 806 a group of andesites corresponding to old eruptive products of Ampato Basal edifice and 807 Ampato Upper edifice; (2) a group of andesites and dacites that represent the main magmatic series covering most eruptive products of Ampato and Sabancaya; and (3) a 808 809 volumetrically minor group of dacites displaying a different geochemical signature (compared with group 2 dacites). On one hand, most eruptive products of Ampato and 810 Sabancaya volcanoes (groups 1 and 2) follow a two-step differentiation model in which 811 primitive mafic magmas generated by partial melting of the metasomatized mantle wedge 812 rise and accumulate at lower crustal reservoirs, where they evolved by AFC processes 813 814 involving garnet and/or amphibole. This step is responsible for the HREE depletion and 815 highly radiogenic signature of ASCV magmas. Trace element and isotope concentrations suggest that the Precambrian Charcani gneiss is the most likely crustal contaminant. At 816 817 upper crustal levels, magmatic evolution is dominated, on one hand by magma mixing between two end-members producing the most common andesites and dacites of group 818 2. On the other hand, group 3 dacites seem to result of upper crust AFC process from 819 primitive magmas different than that produced the main ASCV trend. 820

- 1087
- Table 2. Textural and mineralogical characteristics of Ampato-Sabancaya compound
 volcano. Mineral assemblages for each petrographic type are reported (*Pl* plagioclase, *Ol*

| 1090 | olivine, Opx orthopyroxene, Cpx clinopyroxene, Amp amphibole, Bt biotite, Mag |
|------|---|
| 1091 | Magnetite, Ap Apatite). Mineral abbreviations after Whitney and Evans (2010). |
| 1092 | |

1093 Table 3. Summary of mineralogical characteristics of Ampato-Sabancaya rocks.

1094

Fig. 1. (a) Map showing the locations of the South American volcanic zones: Northern
(NVZ), Central (CVZ), Southern (SVZ) and Austral (AVZ), modified after Stern (2004).
(b) Northernmost part of CVZ in southern Peru (modified after Thouret et al., 2005).
Ampato-Sabancaya compound volcano is in the middle of the Plio-Quaternary volcanic
range in southern Peru, ~70 km NW of the city of Arequipa. (c) View of the western flank

1100 of Ampato and Sabancaya.

1101

Fig. 2. Geological map of ASVC complex overlaid on a hillshade base map generated from a Digital Elevation Model (modified after Samaniego et al., 2016). Sampling sites for lavas and tephra analysed in this study are indicated by red dots. We also include the age determinations available for this volcanic centre.

1106

Fig. 3. Microphotographs of thin sections from Ampato-Sabancaya samples. (a) Andesite 1107 1108 (SA-1165) from Yanajaja stage showing a mineral assemblage composed of plagioclase, clinopyroxene, amphibole, biotite, and Fe-Ti oxides. Note the thin black aureole around 1109 the amphibole and biotite. (b) Dacite (SA-1159) from Ampato Upper showing a mineral 1110 assemblage composed of plagioclase, amphibole, clinopyroxene, and Fe-Ti oxides. (c) 1111 1112 Dacite (SA-1155) from Ampato Upper showing a mineral assemblage composed of plagioclase, clinopyroxene, amphibole, biotite, and Fe-Ti oxides. (d) Rhyolitic pumice 1113 1114 (SA-1142A) showing a mineral assemblage composed of plagioclase and biotite. (e) Dacitic pumice (SA-1127D) from the Corinta tephra-fall deposit composed of plagioclase, clinopyroxene, and Fe-Ti oxides. (**f**) Disequilibrium textures in the andesite (SA-0917) from Sabancaya showing a plagioclase phenocryst with an altered (sieve) rim and a fresh overgrowth rim. Mineral abbreviations are the same as Table 2.

1119

Fig. 4. Major and trace elements variation diagrams. Petrographic fields in the K₂O *vs*. SiO₂ diagram after Peccerillo and Taylor (1976). All major elements (except K₂O), transition elements (e.g., Ni, Cr), Sr, Sm, Zr, and possibly Yb are negatively correlated with SiO₂, while K₂O, Rb, and to some extent La are positively correlated. G1-4 correspond to the four groups identified (see text for more details).

1125

Fig. 5. (a) Trace elements normalized to primitive mantle and (b) REE normalized to 1126 chondritic values (both after Sun and McDonough, 1989) for rocks of the evolutionary 1127 stages of ASCV. Brown area represents normalized composition of lavas and tephras 1128 from the Early andesitic stage (Ampato Basal edifice), as well as to the scoriaceous 1129 1130 tephra-fall and pyroclastic-flow deposits of Ampato Upper edifice (Group 1). Green 1131 area represents normalized composition of lavas from the Moldepampa stage, Ampato Upper edifice, and Sabancaya edifice (Group 2). G1-4 correspond to the four groups 1132 1133 identified.

1134

Fig. 6. (a) ⁸⁷Sr/⁸⁶Sr *vs*. ¹⁴³Nd/¹⁴⁴Nd diagram for Ampato-Sabancaya rocks, compared with other published isotopic data for the CVZ, SVZ, and NVZ (Davidson et al., 1991). (b) SiO₂ *vs*. ⁸⁷Sr/⁸⁶Sr wt.% diagram. Insets depict the evolution of the isotopic composition during fractional crystallization (FC), mixing, and assimilation-fractional crystallization (AFC) processes. Symbols are the same as Fig. 4. 1140

Fig. 7. (a) ²⁰⁸Pb/²⁰⁴Pb and (b) ²⁰⁷Pb/²⁰⁴Pb vs. ²⁰⁶Pb/²⁰⁴Pb diagrams of ASCV bulk rock 1141 compositions. Compositional fields of Pb isotopic values for Andean volcanic zones are 1142 from Ancellin et al. (2017). I= Isotopic fields of the southern Arequipa segment and 1143 northern Toquepala segment; II= Isotopic fields of the northern Arequipa segment; III= 1144 mafic and intermediate magmatic rocks of the Lima segment. In ²⁰⁷Pb/²⁰⁴Pb and 1145 ²⁰⁸Pb/²⁰⁴Pb vs. ²⁰⁶Pb/²⁰⁴Pb diagram, Ampato-Sabancaya rocks plot in the isotopic field of the 1146 1147 southern part of Arequipa segment and northern Toquepala segment of the Peruvian Coastal batholith. DMM is Depleted MORB Mantle (Rehkamper and Hofmann, 1997). 1148 (c) ²⁰⁸Pb/²⁰⁴Pb and (d) ²⁰⁷Pb/²⁰⁴Pb vs. ²⁰⁶Pb/²⁰⁴Pb diagram of ASCV have trends consistent 1149 with assimilation in shallow crust and assimilation in deep crust (MASH processes). CG 1150 is Charcani gneiss. Symbols are the same as Fig. 4. 1151

1152

Fig. 8. Compositional changes of Ampato-Sabancaya's lavas and juvenile pyroclastic products through time. The chronological axis is inverse-logarithmic to account for higher sampling density and wider compositional range in young eruptive products.

1156

Fig. 9. Sr *vs.* SiO₂ contents for Ampato-Sabancaya rocks and Andahua-Huambo volcanic province
with the three end-member involved in the genesis for CVZ magmatism from Blum-Oeste and
Wörner (2016).

1160

Fig. 10. Th and Ni *vs*. Rb diagrams for Ampato-Sabancaya whole-rock samples. The plot Ni *versus* Rb display a large diversity of values which suggest a more complex scenario than simply fractional crystallization (FC). Arrows depict the evolution of magmas 1164 composition during fractional crystallization (FC) and mixing processes. Symbols are the1165 same as Fig. 4.

1166

Fig. 11. a) K/Rb *vs.* Rb diagram. Arrows illustrate differentiation by fractional crystallization and AFC, binary mixing, and variable degrees of partial melting. The curved trend of the Ampato-Sabancaya samples indicate that fractional crystallization alone cannot explain the variation. b) Dy/Yb *vs.* SiO₂ wt.% diagram. The arrows show the expected effects of garnet, amphibole, and plagioclase-pyroxene fractionation. Note that amphibole is the only mineral able to efficiently fractionate MREE over HREE (i.e., Dy/Yb). Legend is given in Fig. 4.

1174

Fig. 12. (a) 87 Sr/ 86 Sr vs. Sr (ppm), (b) Y (ppm), and (c) Co (ppm) vs. 87 Sr/ 86 Sr diagrams 1175 showing the curves of two petrogenetic models (indicated by numbers in parentheses) 1176 such as assimilation-fractional crystallization (AFC) and magma mixing for Ampato-1177 1178 Sabancaya magmas. (1) AFC model showing the effects of contamination of sample SA-1179 1033E by the Charcani gneiss (James, 1982; Boily et al., 1990). AFC parameters are given in the figure. Circles in the curves represent the remaining proportion of melt after 1180 assimilation. Curves have been calculated according to DePaolo (1981). (2) Bulk mixing 1181 1182 models between a basic end-member (sample SA-1033E) and a silicic end-member (sample SA-0914). Symbols are the same as Fig. 4. 1183

1184

Fig. 13. (a) Rb/V versus 1/V diagram for Ampato-Sabancaya wholerock samples. The linear trend highlights a binary mixing process (Schiano et al., 2010). b) Plot of Rb versus Rb/V for lavas from Ampato-Sabancaya illustrating mixing curves. A schematic C^{I} vs. C^{I}/C^{C} and $1/C^{C}$ vs. C^{I}/C^{C} diagrams are also shown with curves illustrating melt

48

compositions produced by mixing, fractional crystallization, and partial meltingprocesses. Symbols are the same as Fig. 4.

1191

Fig. 14. Schematic diagrams illustrating the two mechanisms for andesite and dacites formation of Ampato-Sabancaya in the CVZ. (A) Mechanisms for andesite and dacites formation of group 1 and 2. (B) Mechanisms for dacites formation of group 3 (modified after Burns and de Silva, 2023).

1196

SEM 1. Selected plagioclase, clinopyroxene, orthopyroxene, amphibole, biotite, olivine,
magnetite, and ilmenite compositions (in wt.%) from Ampato-Sabancaya compound
volcano lavas.

SEM 2. Major element (wt.%), trace element (ppm), Sr, Nd and Pb isotopic ratios for theAmpato-Sabancaya volcanic complex.

1202 SEM 3. a) Ab-An-Or ternary projections for Ampato-Sabancaya plagioclase. b) Mg/(Mg

1203 + Fe²⁺) versus Si (a.p.f.u., atoms per formula unit) diagram for calcic amphibole

1204 (nomenclature after Leake et al., 1997) showing that Ampato-Sabancaya amphiboles are

edenite-pargasite (with: $Ca_B \ge 1.50$, (Na+K)_A ≥ 0.50 and Ti<0.5) and Magnesiohornblende-

- 1206 tschermakite (with: $Ca_B \ge 1.50$, (Na+K)_A<0.50 and Ca_A<0.5).
- 1207 SEM 4. Pyroxene compositions for Ampato-Sabancaya rocks. (a) En-Wo-Fs ternary
- 1208 projections for pyroxene and (b) pyroxenes discriminated by Cr₂O₃ and Mg# contents.

^aXRF analyses of bulk juvenile clasts on an anhydrous basis; $n \, n^{\circ}$. of samples

^bRange of microprobe analyses of phenocrysts

^cRange of microprobe analyses; Mg# [where Mg# = 100^{*}Mg/(Mg + Fe^T) in mol.%, and Fe^T is total iron as Fe²⁺]
